NATHAN AND OSKI'S HEMATOLOGY AND ONCOLOGY OF INFANCY AND CHILDHOOD

NATHAN AND OSKI'S HEMATOLOGY AND ONCOLOGY OF INFANCY AND CHILDHOOD

Stuart H. Orkin, MD
David G. Nathan Professor of Pediatrics
Harvard Medical School
Chair, Department of Pediatric Oncology
Dana-Farber Cancer Institute
Boston Children's Hospital
Investigator, Howard Hughes Medical Institute
Boston, Massachusetts

David E. Fisher, MD, PhD
Chief, Department of Dermatology
Director, Cutaneous Biology Research Center
Massachusetts General Hospital
Director, Melanoma Program
Massachusetts General Hospital Cancer Center
Boston, Massachusetts

David Ginsburg, MD
James V. Neel Distinguished University Professor
Departments of Internal Medicine, Pediatrics and Communicable Diseases, and Human Genetics
Investigator, Howard Hughes Medical Institute
University of Michigan Medical School
Ann Arbor, Michigan

A. Thomas Look, MD
Professor of Pediatrics
Harvard Medical School
Vice Chair for Research
Department of Pediatric Oncology
Dana-Farber Cancer Institute
Boston Children's Hospital
Boston, Massachusetts

Samuel E. Lux, MD
Robert A. Stranahan Professor of Pediatrics
Harvard Medical School
Chief Emeritus, Hematology/Oncology
Boston Children's Hospital
Boston, Massachusetts

David G. Nathan, MD
President Emeritus
Dana-Farber Cancer Institute
Physician-in-Chief Emeritus
Boston Children's Hospital
Stranahan Distinguished Professor of Pediatrics and Professor of Medicine
Harvard Medical School
Boston, Massachusetts

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Library of Congress Cataloging-in-Publication Data

Nathan and Oski's hematology and oncology of infancy and childhood / [edited by] Stuart H. Orkin, David E. Fisher, A. Thomas Look, Samuel E. Lux, IV, David Ginsburg, David G. Nathan.—Eighth edition.
p. ; cm.
Hematology and oncology of infancy and childhood
Preceded by: Nathan and Oski's hematology of infancy and childhood / edited by Stuart H. Orkin … [et al.]. 7th ed. c2009; and, Oncology of infancy and childhood / [edited by] Stuart H. Orkin … [et al.]. 1st ed. c2009.
Includes bibliographical references and index.
ISBN 978-1-4557-5414-4 (hardcover : alk. paper)
I. Orkin, Stuart H., editor. II. Title: Hematology and oncology of infancy and childhood.
[DNLM: 1. Hematologic Diseases. 2. Neoplasms. 3. Child. 4. Infant. WS 300]

CONTRIBUTORS

Sarah Alexander, MD
Assistant Professor, University of Toronto, Clinical Director of Hematology/Oncology, Hospital for Sick Children, Toronto, Canada
Pediatric Lymphoma

James Amatruda, MD, PhD
Associate Professor of Pediatrics, Molecular Biology and Internal Medicine, UT Southwestern Medical Center, Dallas, Texas
Pediatric Germ Cell Tumors

Megan E. Anderson, MD
Attending, Department of Orthopedic Surgery, Children's Hospital Boston; Attending, Department of Orthopedic Surgery, Beth Israel Deaconess Medical Center; Instructor, Department of Orthopedic Surgery, Harvard Medical School, Boston, Massachusetts
Pediatric Surgical Oncology

Pedram Argani, MD
Director of Immunohistochemistry Laboratory, Johns Hopkins Hospital, Baltimore, Maryland
Pediatric Renal Tumors

Scott A. Armstrong, MD, PhD
Leukemia Center, Human Oncology and Pathogenesis Program and Department of Pediatrics, Memorial Sloan Kettering Cancer Center, New York, New York
Infant Leukemias

Pratiti Bandopadhayay, MD, PhD
Pediatric Medical Neuro-Oncology, Department of Pediatric Oncology, Dana-Farber/Boston Children's Cancer and Blood Disorders Center, Boston, Massachusetts
Tumors of the Brain and Spinal Cord

Raymond Barfield, MD, PhD
Associate Professor of Pediatrics and Christian Philosophy, Director, Pediatric Quality of Life and Palliative Care Program, Director, Theology, Medicine, and Culture, Duke University, Durham, North Carolina
Ethical Considerations in Pediatric Oncology Clinical Trials

Frederic G. Barr, MD, PhD
Senior Investigator and Deputy Chief, Laboratory of Pathology, National Cancer Institute, Bethesda, Maryland
Rhabdomyosarcoma

Kenneth A. Bauer, MD
Professor of Medicine, Harvard Medical School; Chief, Hematology Section, Medical Service, VA Boston Healthcare System, Jamaica Plain, Massachusetts; Director, Thrombosis Clinical Research, Department of Medicine, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Rare Hereditary Coagulation Factor Abnormalities
Inherited Disorders of Thrombosis and Fibrinolysis

Susanne H.C. Baumeister, MD
Instructor of Pediatrics, Harvard Medical School; Attending Physician, Pediatric Hematology and Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusetts
Immunotherapy of Cancer

Charles B. Berde, MD, PhD
Chief, Division of Pain Medicine, Department of Anesthesiology, Perioperative and Pain Medicine, Boston Children's Hospital; Professor of Anesthesia and Pediatrics, Harvard Medical School, Boston, Massachusetts
Symptom Management in Children with Cancer

Guillaume Bergthold, MD, PhD
Service de Pédiatrie III, Pédiatrie Onco-Hématologie, Progression Tumorale et Microenvironnement, Approches Translationnelles et Épidémiologie, Université de Strasbourg, Strasbourg, France
Tumors of the Brain and Spinal Cord

Jason N. Berman, MD
Associate Professor, Pediatrics, Microbiology and Immunology, and Pathology, Dalhousie University, IWK Health Centre, Halifax, Nova Scotia, Canada
Pediatric Myeloid Leukemia, Myelodysplasia, and Myeloproliferative Disease

Monica Bessler, MD, PhD
Professor of Pediatrics, The Children's Hospital of Philadelphia; Professor, Department of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Inherited Bone Marrow Failure Syndromes

Smita Bhatia, MD, MPH
Chair, Population Sciences, City of Hope Medical Center, Duarte, California
Epidemiology of Leukemia in Childhood

Amy Louise Billett, MD
Director of Safety and Quality, Dana-Farber/Boston Children's Cancer and Blood Disorders Center; Associate Professor of Pediatrics, Harvard Medical School, Boston, Massachusetts
Symptom Management in Children with Cancer

Deborah Billmire, MD
Professor of Surgery, Indiana University School of Medicine, Indianapolis, Indiana
Pediatric Germ Cell Tumors

Michael Bishop, MD, MS
Staff Physician, Department of Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee
Rare Tumors of Childhood

Francisco A. Bonilla, MD, PhD
Director, Clinical Immunology Program, Division of Immunology, Boston Children's Hospital; Associate Professor of Pediatrics, Harvard Medical School, Boston, Massachusetts
Primary Immunodeficiency Diseases

Niels Borregaard, MD, DMedSci
Professor of Hematology, National University Hospital; Professor of Hematology, Faculty of Health Sciences, University of Copenhagen, Copenhagen, Denmark
Phagocyte System and Disorders of Granulopoiesis and Granulocyte Function

Brian Branchford, MD
Instructor of Pediatrics, Hematology/Oncology/Bone Marrow Transplant, University of Colorado School of Medicine, Children's Hospital Colorado, Aurora, Colorado
Approach to the Child with a Suspected Bleeding Disorder

[†]Patricia A. Branowicki, MS, RN, NEA-BC, FAAN
Associate Chief Nurse, Medicine Patient Services, Boston Children's Hospital; Associate Chief Nurse, Pediatric Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusetts
Nursing Care of Patients with Childhood Cancer

Carlo Brugnara, MD
Professor of Pathology, Harvard Medical School; Director of the Hematology Laboratory, Department of Laboratory Medicine, Boston Children's Hospital, Boston, Massachusetts
Diagnostic Approach to the Anemic Patient
Appendices: Reference Values in Infancy and Childhood

Kathleen Brummel-Ziedins, PhD
Associate Professor of Biochemistry, University of Vermont, Burlington, Vermont
Blood Coagulation

T. Andrew Burrow, MD
Assistant Professor of Clinical Pediatrics, University of Cincinnati Department of Pediatrics, Cincinnati Children's Hospital, Cincinnati, Ohio
Lysosomal Storage Diseases

Alan B. Cantor, MD, PhD
Assistant Professor of Pediatrics, Division of Pediatric Hematology and Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, Harvard Medical School, Boston, Massachusetts
Hemostasis in the Newborn and Infant

Ralph Carmel, MD
Department Medicine, New York University Medical Center, New York, New York
Megaloblastic Anemia

Susan N. Chi, MD
Clinical Director, Pediatric Neuro-Oncology, Department of Pediatric Oncology, Dana-Farber/Boston Children's Cancer and Blood Disorders Center, Boston, Massachusetts
Tumors of the Brain and Spinal Cord

Stella T. Chou, MD
Assistant Professor of Pediatrics, Division of Hematology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Autoimmune Hemolytic Anemia

Susanne B. Conley, MSN, RN, CPON
Clinical Nurse Specialist, Dana-Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusetts
Nursing Care of Patients with Childhood Cancer

George Q. Daley, MD, PhD
Samuel E. Lux, IV, MD, Professor of Hematology and Oncology, Boston Children's Hospital; Director, Stem Cell Transplantation Program, Dana-Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusettes
Anatomy and Physiology of Hematopoiesis

Ian J. Davis, MD, PhD
Associate Professor of Pediatrics and Genetics, Member, Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Nonrhabdomyosarcoma Soft Tissue Sarcomas and Other Soft Tissue Tumors

Barbara A. Degar, MD
Senior Physician of Pediatric Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital; Assistant Professor, Department of Pediatrics, Harvard Medical School, Boston, Massachusetts
Histiocytoses

[†]Deceased.

Claire F. Dickson
Menzies Research Institute Tasmania, University of Tasmania, Hobart, Tasmania, Australia
Normal and Abnormal Hemoglobins

Lisa Diller, MD
Professor of Pediatrics, Harvard Medical School; Chief Medical Officer, Dana-Farber/Boston Children's Cancer and Blood Disorders Center, Boston, Massachusetts
Childhood Cancer Survivorship

Mary C. Dinauer, MD, PhD
Fred M. Saigh Distinguished Chair of Pediatric Research, Department of Pediatrics, Department of Pathology and Immunology, Washington University School of Medicine, St. Louis, Missouri
Phagocyte System and Disorders of Granulopoiesis and Granulocyte Function

Barthelemy Diouf, PhD, PharmD
Staff Scientist of Pharmaceutical Sciences, St. Jude Children's Research Hospital, Memphis, Tennessee
Cancer Chemotherapy for Pediatric Patients

Jorge Di Paola, MD
Associate Professor of Pediatrics and Human Genetics, Hematology/Oncology/Bone Marrow Transplant, University of Colorado School of Medicine, Children's Hospital Colorado, Aurora, Colorado
Approach to the Child with a Suspected Bleeding Disorder
Hemophilia and von Willebrand Disease

Jeffrey S. Dome, MD, PhD
Chief of Hematology and Oncology, Children's National Medical Center, Washington, District of Columbia
Pediatric Renal Tumors

Elissa Downs, MD, MPH
Pediatric Gastroenterology Fellow, Department of Pediatric Gastroenterology, Hepatology, and Nutrition, University of Minnesota, Minneapolis, Minnesota
Neonatal Jaundice and Disorders of Bilirubin Metabolism

Glenn Dranoff, MD
Professor of Medicine, Department of Medical Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, and Harvard Medical School, Boston, Massachusetts
Immunotherapy of Cancer

Steven G. DuBois, MD, MS
Associate Professor, Department of Pediatrics, University of California, San Francisco School of Medicine; Attending Physician, Department of Pediatrics, University of California, San Francisco, Benioff Children's Hospital, San Francisco, California
Ewing Sarcoma

Christine N. Duncan, MD, MSc
Assistant Professor of Pediatric Hematology and Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusetts
Principles of Bone Marrow and Stem Cell Transplantation

Janet Duncan, PNP
Program Founder and Director of Comfort Care Research and Program Development, Mattel Children's Hospital; Adjunct Assistant Professor of Pediatrics, University of California Los Angeles, Los Angeles, California
Palliative Care in Pediatric Oncology

Michael Dyer, MD
Investigator, HHMI, Member, Department of Developmental Neurobiology, Head, Division of Developmental Biology, St. Jude Children's Research Hospital, Memphis, Tennessee
Retinoblastoma

Alaa El-Haddad, MD
Professor of Pediatric Hematology/Oncology, Dean, National Cancer Institute, Cairo University; Director of Pediatric Bone Marrow Transplant, Children's Cancer Hospital, Cairo, Egypt
Principles of Bone Marrow and Stem Cell Transplantation

Elana Evan, PhD
Program Founder and Director of Comfort Care Research and Program Development, Mattel Children's Hospital; Adjunct Assistant Professor of Pediatrics, University of California Los Angeles, Los Angeles, California
Palliative Care in Pediatric Oncology

William E. Evans, PharmD
Director and CEO of St. Jude Children's Research Hospital; Professor of Pediatrics and Clinical Pharmacy, University of Tennessee, Colleges of Medicine and Pharmacy; Member (Professor) of Pharmaceutical Sciences, St. Jude Children's Research Hospital, Memphis, Tennessee
Cancer Chemotherapy for Pediatric Patients

Carolyn A. Felix, MD
Professor of Pediatrics, University of Pennsylvania School of Medicine; Attending Physician, Division of Oncology, Joshua Kahan Endowed Chair in Pediatric Leukemia Research, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Cytogenetic and Molecular Pathology of Pediatric Cancer

Adolfo A. Ferrando, MD, PhD
Associate Professor of Pediatrics, Associate Professor of Pathology and Cell Biology, Associate Profressor, Institute for Cancer Genetics, Columbia University Medical Center, New York, New York
Pediatric Lymphoma

Brian T. Fisher, DO, MPH, MSCE
Assistant Professor of Pediatrics, Division of Infectious Diseases, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, Pennsylvania
Infectious Disease in the Pediatric Cancer Patient

David E. Fisher, MD, PhD
Chief, Department of Dermatology, Director, Cutaneous Biology Research Center, Massachusetts General Hospital; Director, Melanoma Program, Massachusetts General Hospital Cancer Center, Boston, Massachusetts
Nonrhabdomyosarcoma Soft Tissue Sarcomas and Other Soft Tissue Tumors

Mark D. Fleming, MD
S. Burt Wolbach Professor and Chairman, Department of Pathology, Boston Children's Hospital, Boston, Massachusetts
Disorders of Iron and Copper Metabolism, the Sideroblastic Anemias, and Lead Toxicity
Histiocytoses

Jonathan A. Fletcher, MD
Pathologist, Brigham and Women's Hospital; Associate Professor of Pathology and Pediatrics, Harvard Medical School, Boston, Massachusetts
Cytogenetic and Molecular Pathology of Pediatric Cancer

Veronica Flood, MD
Associate Professor of Pediatric Hematology and Oncology, Medical College of Wisconsin, Milwaukee, Wisconsin
Hemophilia and von Willebrand Disease

A. Lindsay Frazier, MD, ScM
Institute Physician of Pediatric Hematology and Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital; Associate Professor of Pediatrics, Harvard Medical School; Associate Professor of Epidemiology, Harvard School of Public Health, Boston, Massachusetts
Pediatric Germ Cell Tumors

Patrick G. Gallagher, MD
Professor of Pediatrics, Pathology, and Genetics, Yale University School of Medicine, New Haven, Connecticuit
The Neonatal Erythrocyte and Its Disorders

Glenn Gardener, MB, BS
Director, Center for Maternal Fetal Medicine, Mater Mothers' Hospital, Brisbane, Australia
Immune Hemolytic Disease

Mark C. Gebhardt, MD
Surgeon-in-Chief, Department of Orthopaedic Surgery, Beth Israel Deaconess Medical Center; Orthopedic Surgeon, Department of Orthopedics, Children's Hospital; Frederick W. and Jane M. Ilfeld Professor of Orthopedic Surgery, Department of Orthopedic Surgery, Harvard Medical School, Boston, Massachusetts
Pediatric Surgical Oncology

David A. Gell, PhD
Menzies Research Institute Tasmania, University of Tasmania, Hobart, Tasmania, Australia
Normal and Abnormal Hemoglobins

Rani E. George, MD, PhD, MRCP
Associate Professor of Pediatrics, Harvard Medical School; Department of Pediatric Hematology and Oncology, Dana Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusetts
Neuroblastoma

Joan Cox Gill, MD
Professor of Pediatrics and Medicine, Medical College of Wisconsin; Senior Investigator, Medical Sciences Institute, BloodCenter of Wisconsin, Milwaukee, Wisconsin
Hemophilia and von Willebrand Disease

John M. Goldberg, MD
Assistant Professor of Clinical Pediatrics, Director, Pediatric Oncology Early Phase Clinical Trials Program, UM Sylvester Comprehensive Cancer Center, Division of Pediatric Hematology and Oncology, Miami, Florida
Rare Tumors of Childhood

Neil Goldenberg, MD, PhD
Director of Research, Chief Research Officer, All Children's Hospital–Johns Hopkins Medicine, St. Petersburg, Florida
Acquired Disorders of Hemostasis

Liliana C. Goumnerova, MD, FRCSC, FAANS
Director for Pediatric Neurosurgical Oncology, Boston Children's Hospital/Dana Farber Cancer Institute; Associate Professor of Neurosurgery, Harvard Medical School, Boston, Massachusetts
Tumors of the Brain and Spinal Cord

Glenn R. Gourley, MD
Professor of Pediatrics, Research Director, Pediatric Gastroenterology, University of Minnesota, Minneapolis, Minnesota
Neonatal Jaundice and Disorders of Bilirubin Metabolism

Gregory A. Grabowski, MD
Human Genetics, Cincinnati Children's Research Foundation, Cincinnati, Ohio
Lysosomal Storage Diseases

Rachael F. Grace, MD, MMSc
Assistant Professor of Pediatrics, Harvard Medical School; Director, Hematology Clinic, Boston Children's Hospital, Dana-Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusetts
Hematologic Manifestations of Systemic Diseases

Eric Gratias, MD, FAAP
Associate Professor of Pediatric Hematology and Oncology, Children's Hospital at Erlanger; Associate Professor of Pediatrics, University of Tennessee College of Medicine Chattanooga, Chattanooga, Tennessee
Oncologic Emergencies

Mel Greaves, PhD
Professor of Molecular Pathology, Institute of Cancer Research, London, United Kingdom
Origins and Evolution of Pediatric Cancers

Adam L. Green, MD
Instructor of Pediatrics, University of Colorado Denver; Attending Physician, Center for Cancer and Blood Disorders, Children's Hospital Colorado, Denver, Colorado
Tumors of the Brain and Spinal Cord

Holcombe E. Grier, MD
Professor, Department of Pediatrics, Harvard Medical School, Dana-Farber/Boston Children's Cancer and Blood Disorders Center, Boston, Massachusetts
Ewing Sarcoma

Alejandro Gutierrez, MD
Assistant Professor of Pediatrics, Division of Hematology and Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, and Harvard Medical School, Boston, Massachusetts
Acute Lymphoblastic Leukemia

W. Nicholas Haining, BM, BCh
Assistant Professor of Pediatrics, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, and Harvard Medical School, Boston, Massachusetts
Principles of Bone Marrow and Stem Cell Transplantation

Katherine Amberson Hajjar, MD
Brine Family Professor and Chair, Cell and Developmental Biology, Professor of Pediatrics, Professor of Medicine, Weill Cornell Medical College, New York, New York
Molecular Basis of Fibrinolysis

Matthew M. Heeney, MD
Associate Chief of Hematology, Division of Hematology and Oncology, Boston Children's Hospital; Assistant Professor of Pediatrics, Harvard Medical School, Boston, Massachusetts
Sickle Cell Disease

Kathleen E. Houlahan, MSN, MHA, RN, NE-BC
Director, Nursing/Patient Care Services, Pediatric Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusetts
Nursing Care of Patients with Childhood Cancer

Hiroto Inaba, MD, PhD
Associate Member (Associate Professor) of Oncology, St. Jude Children's Research Hospital; Associate Professor of Pediatrics, University of Tennessee Health Science Center, Memphis, Tennessee
Cancer Chemotherapy for Pediatric Patients

Katherine Janeway, MD, MMSc
Assistant Professor of Pediatrics, Harvard Medical School; Senior Physician of Pediatric Oncology, Dana-Farber/Boston Children's Cancer and Blood Disorders Center, Boston, Massachusetts
Osteosarcoma

Lisa B. Kenney, MD, MPH
Assistant Professor of Pediatrics, Harvard Medical School; Senior Physician, Dana-Farber/Boston Children's Cancer and Blood Disorders Center, Boston, Massachusetts
Childhood Cancer Survivorship

Alex Kentsis, MD, PhD
Department of Pediatrics, Molecular Pharmacology and Chemistry Program, Memorial Sloan-Kettering Cancer Center, Sloan-Kettering Institute, New York, New York
Genetics and Epigenetics of Childhood Cancers

Mark W. Kieran, MD, PhD
Director of Pediatric Medical Neuro-Oncology, Department of Pediatric Oncology, Dana-Farber/Boston Children's Cancer and Blood Disorders Center, Boston, Massachusetts
Tumors of the Brain and Spinal Cord

Nancy E. Kline, PhD, RN, CPNP, FAAN
Director, Nursing Research, Department of Medicine Patient Services, Boston Children's Hospital, Boston, Massachusetts
Nursing Care of Patients with Childhood Cancer

Rachel Kobos, MD
Department of Pediatrics, Memorial Sloan Kettering Cancer Center, New York, New York
Infant Leukemias

Eric Kodish, MD
Director, Center for Ethics, Humanities, and Spiritual Care, FJ O'Neill Professor and Chair, Department of Bioethics, Cleveland Clinic, Cleveland, Ohio
Ethical Considerations in Pediatric Oncology Clinical Trials

Andrew Y. Koh, MD
Assistant Professor, Director of Pediatric Hematopoietic Stem Cell Transplantation, Pediatrics, University of Texas Southwestern Medical Center, Dallas, Texas
Infectious Disease in the Pediatric Cancer Patient

James P. Kushner, MD
M.M.Wintrobe Distinguished Professor of Medicine Emeritus, Department of Internal Medicine, Division of Hematology, University of Utah School of Medicine, Salt Lake City, Utah
Porphyrias

Dominic P. Kwiatkowski, FRCP
Group Head/PI and Consultant Physician, Wellcome Trust Center for Human Genetics, University of Oxford, Oxford, United Kingdom
Hematologic Manifestations of Systemic Diseases in Children of the Developing World

Michele P. Lambert, MD, MTR
Assistant Professor of Pediatrics, Perelman School of Medicine, University of Pennsylvania; Attending Physician, Division of Hematology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Inherited Platelet Disorders

Leslie E. Lehmann, MD
Assistant Professor of Pediatric Hematology and Oncology, Dana-Farber/Boston Children's Cancer and Blood Disorder Center, Boston, Massachusetts
Principles of Bone Marrow and Stem Cell Transplantation

Nancy D. Leslie, MD
Professor of Pediatrics, Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Lysosomal Storage Diseases

Stephen L. Lessnick, MD, PhD
Director, Center for Children's Cancer Research, Jon and Karen Huntsman Presidential Professor in Cancer Research, Huntsman Cancer Institute; Professor of Pediatrics, Division of Pediatric Hematology and Oncology, University of Utah, Salt Lake City, Utah
Ewing Sarcoma

Keith L. Ligon, MD, PhD
Department of Pathology, Dana-Farber Cancer Institute, Boston Children's Hospital; Department of Pathology, Division of Neuropathology, Brigham and Women's Hospital, Boston, Massachusetts
Tumors of the Brain and Spinal Cord

Helen G. Liley, MB, ChB
Senior Staff Specialist, Newborn Services, Mater Mothers' Hospital, South Brisbane, Queensland; Associate Professor, Pediatrics and Child Health, School of Medicine, The University of Queensland, Brisbane, Queensland
Neonatal Immune Hemolytic Disease

Corinne M. Linardic, MD, PhD
Associate Professor of Pediatrics, Division of Hematology and Oncology, Associate Professor of Pharmacology and Cancer Biology, Duke University School of Medicine, Durham, North Carolina
Rhabdomyosarcoma

Robert B. Lindell, MD
Division of General Pediatrics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Genetic Predisposition to Cancer

Daniel C. Link, MD
Alan and Edith Wolff Professor, Department of Medicine, Washington University, St. Louis, Missouri
Inherited Bone Marrow Failure Syndromes

Cori Liptak, PhD
Senior Psychologist, Director of Pediatric Neurooncology Survivorship Behavioral Health Programs, Dana-Farber/Boston Children's Center for Cancer and Blood-Related Disorders; Instructor, Department of Psychiatry, Harvard Medical School, Boston, Massachusetts
Psychosocial Care of the Child and Family

A. Thomas Look, MD
Professor of Pediatrics, Harvard Medical School; Vice Chair for Research, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusetts
Pediatric Myeloid Leukemia, Myelodysplasia, and Myeloproliferative Disease

Enrico Lopriore, MD, PhD
Pediatrician-Neonatologist, Leiden University Medical Center, The Hague, Netherlands
Immune Hemolytic Disease

Samuel E. Lux, MD
Robert A. Stranahan Professor of Pediatrics, Harvard Medical School; Chief Emeritus, Hematology/Oncology, Boston Children's Hospital, Boston, Massachusetts
Red Cell Membrane
Disorders of the Red Cell Membrane

Lucio Luzzatto, MD
Istituto Toscano Tumori and Department of Haematology, University of Florence, Florence, Italy
Glucose-6-Phosphate Dehydrogenase Deficiency

Shannon M. MacDonald, MD
Radiation Oncology, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts
Pediatric Radiation Oncology

Jennifer W. Mack, MD, MPH
Assistant Professor of Pediatrics, Department of Pediatric Hematology and Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital; Assistant Professor of Pediatrics, Harvard Medical School, Boston, Massachusetts
Palliative Care in Pediatric Oncology

Peter E. Manley, MD
Director, Pediatric Neuro-Oncology Outcomes Clinic, Dana-Farber Boston Children's Cancer and Blood Disorders Center; Instructor in Pediatrics, Harvard Medical School, Boston, Massachusetts
Tumors of the Brain and Spinal Cord

Kenneth G. Mann, PhD
Professor Emeritus of Biochemistry and Medicine, College of Medicine, University of Vermont, Burlington, Vermont; Chairman, Haematologic Technologies Incorporated, Essex Junction, Vermont
Blood Coagulation

Karen Jean Marcus, MD
Pediatric Radiation Oncology, Dana-Farber/Boston Children's Cancer and Blood Disorders Center; Associate Professor of Radiation Oncology, Harvard Medical School, Boston, Massachusetts
Pediatric Radiation Oncology
Tumors of the Brain and Spinal Cord

Philip J. Mason, PhD
Professor of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Inherited Bone Marrow Failure Syndromes

William C. Mentzer, Jr., MD
Professor Emeritus of Pediatrics, University of California, San Francisco, San Francisco, California
Pyruvate Kinase Deficiency and Disorders of Glycolysis

Robert R. Montgomery, MD
Senior Investigator, Blood Research Institute, BloodCenter of Wisconsin; Professor of Pediatric Hematology and Pediatrics, Medical College of Wisconsin, Milwaukee, Wisconsin
Hemophilia and von Willebrand Disease

Andres E. Morales La Madrid, MD
Neuro-Oncology Unit, Department of Pediatric Hematology and Oncology, St. Joan de Déu Children's Hospital, Barcelona, Spain
Tumors of the Brain and Spinal Cord

Elizabeth A. Mullen, MD
Attending Physician of Pediatric Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital; Associate Professor of Pediatrics, Harvard Medical School, Boston, Massachusetts
Pediatric Renal Tumors
Oncologic Emergencies

David G. Nathan, MD
President Emeritus, Dana-Farber Cancer Institute; Physician-in-Chief Emeritus, Boston Children's Hospital; Stranahan Distinguished Professor of Pediatrics and Professor of Medicine, Harvard Medical School, Boston, Massachusetts
Diagnostic Approach to the Anemic Patient
Thalassemias

Peter E. Newburger, MD
Ali and John Pierce Professor of Pediatric Hematology and Oncology, Department of Pediatrics, University of Massachusetts Medical School, Worcester, Massachusetts
Phagocyte System and Disorders of Granulopoiesis and Granulocyte Function

Debra K. Newman, PhD
Investigator, Blood Research Institute, BloodCenter of Wisconsin, Milwaukee, Wisconsin
Platelets and the Vessel Wall

Peter J. Newman, PhD
Vice President for Research, BloodCenter of Wisconsin; Professor, Departments of Pharmacology and Cellular Biology, Medical College of Wisconsin, Milwaukee, Wisconsin
Platelets and the Vessel Wall

Kim E. Nichols, MD
Chief, Division of Hereditary Cancer Predisposition, St. Jude Children's Research Hospital, Division of Oncology, Memphis, Tennessee
Genetic Predisposition to Cancer

Luigi D. Notarangelo, MD
Professor of Pediatrics and Pathology, Department of Medicine, Division of Immunology, Children's Hospital Boston, Harvard Medical School, Boston, Massachusetts
Primary Immunodeficiency Diseases

John S. Olson, PhD
Ralph and Dorothy Looney Professor, Department of Biochemistry and Cell Biology, Rice University, Houston, Texas
Normal and Abnormal Hemoglobins

Stuart H. Orkin, MD
David G. Nathan Professor of Pediatrics, Harvard Medical School; Chair, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital; Investigator, Howard Hughes Medical Institute, Boston, Massachusetts
Thalassemias

[†]Frank A. Oski, MD
Distinguished Service Professor, Johns Hopkins University School of Medicine, Baltimore, Maryland
Diagnostic Approach to the Anemic Patient

[†]Deceased.

Maureen J. O'Sullivan, MD, MBBCh
Professor of Histopathology, University of Dublin, Trinity College; Consultant Pediatric Pathologist, Department of Pathology, Our Lady's Children's Hospital, Crumlin; Principal Investigator of Cancer Genetics, The National Children's Research Centre, Crumlin, Dublin, Ireland
Cytogenetic and Molecular Pathology of Pediatric Cancer

Sung-Yun Pai, MD
Assistant Professor of Pediatrics, Department of Medicine, Boston Children's Hospital; Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital, Boston, Massachusetts
Immune Response

Alberto S. Pappo, MD
Director, Solid Tumor Division, St. Jude Children's Research Hospital, Memphis, Tennessee
Rare Tumors of Childhood

Charles J. Parker, MD
Professor of Medicine, Division of Hematology and Hematologic Malignancies, University of Utah School of Medicine, Salt Lake City, Utah
Paroxysmal Nocturnal Hemoglobinuria

Antonio R. Perez-Atayde, MD
Director of Special Techniques and Diagnostic Surgical Pathology, Boston Children's Hospital; Associate Professor of Pathology, Harvard Medical School, Boston, Massachusetts
Nonrhabdomyosarcoma Soft Tissue Sarcomas and Other Soft Tissue Tumors

John D. Phillips, PhD
Associate Professor of Medicine, University of Utah School of Medicine, Salt Lake City, Utah
Porphyrias

Steven Pipe, MD
Professor of Pediatrics and Pathology, University of Michigan, Ann Arbor, Michigan
Acquired Disorders of Hemostasis

Vincenzo Poggi, MD
Chief of Oncology, AORN Santobono-Pausilipon, Naples, Italy
Glucose-6-Phosphate Dehydrogenase Deficiency

Mortimer Poncz, MD
Division Chief of Hematology, Department of Pediatrics, Children's Hospital of Philadelphia, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania
Inherited Platelet Disorders

Sanjay P. Prabhu, MBBS, FRCR
Assistant Professor of Radiology, Harvard Medical School; Director, Advanced Image Analysis Lab, Boston Children's Hospital, Boston, Massachusetts
Tumors of the Brain and Spinal Cord
Imaging in the Evaluation and Management of Childhood Cancer

Carlos E. Prada, MD
Assistant Professor of Human Genetics, Assistant Director, Biochemical Genetics Laboratory, Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio; Director, Centro de Medicina Genómica y Metabolismo, Fundación Cardiovascular de Colombia, Bucaramanga, Santander, Colombia
Lysosomal Storage Diseases

Christopher J. Recklitis, PhD, MPH
Director of Research and Support Services, Perini Family Survivors' Center, Dana-Farber Cancer Institute, Boston Children's Hospital; Assistant Professor, Department of Pediatrics, Harvard Medical School, Boston, Massachusetts
Psychosocial Care of the Child and Family

Ellis L. Reinherz, MD
Dana-Farber Cancer Institute, Boston Children's Hospital, Harvard Medical School, Boston, Massachusetts
Immune Response

Charles W.M. Roberts, MD, PhD
Associate Professor of Pediatric Oncology, Dana-Farber Cancer Institute, Boston Children's Hospital; Associate Professor of Pediatric Oncology, Harvard Medical School, Boston, Massachusetts
Genetics and Epigenetics of Childhood Cancers

David J. Roberts, MB ChB, D Phil
Consultant Hematologist, National Health Service Blood and Transplant, John Radcliffe Hospital; Professor of Haematology, Nuffield Department of Clinical Laboratory Sciences, University of Oxford, Oxford, England
Hematologic Manifestations of Systemic Diseases in Children of the Developing World

Leslie L. Robison, PhD
Chair, Epidemiology and Cancer Control, St. Jude Children's Research Hospital, Memphis, Tennessee
Epidemiology of Leukemia in Childhood

Nathan J. Robison, MD
Assistant Professor of Pediatrics, University of Southern California Keck School of Medicine, Division of Hematology/Oncology and BMT, Children's Hospital Los Angeles, Los Angeles, California

Grousbeck Professor of Pediatrics, Department of Medicine—Hematology and Oncology, HHMI/ Boston Chilldren's Hospital, Boston, Massachusettes
Anatomy and Physiology of Hematopoiesis

PREFACE

On behalf of the editors, I welcome you to the eighth edition of *Nathan and Oski's Hematology of Infancy and Childhood*, which has been renamed *Nathan and Oski's Hematology and Oncology of Infancy and Childhood* to reflect the new format begun with the last edition. The classic *Nathan and Oski* text continues to evolve in concert with development in the field of pediatric hematology and oncology. Four decades ago David Nathan and Frank Oski had the vision of creating a resource for students, practitioners, and clinical and basic investigators in which pathophysiology relating to diseases of children would inform clinical care and research in the present and for the future. They hoped to stimulate bench-to-bedside and bedside-to-bench activities in order to understand and treat pediatric patients with hematologic disorders and cancer. The first six editions were decidedly hematology-centric. They concentrated on normal blood cells and their abnormalities, hemostasis, and immune disorders. Except for relatively brief discussion of childhood leukemias, the emphasis was on what might be classified as non-malignant hematology. In recognition of the enormous growth of interest, new knowledge, and treatment possibilities in pediatric oncology, we expanded the scope of the seventh edition with extensive coverage of cancer therapeutics, solid tumors, and oncologic supportive care. In some respects the seventh edition was an experiment. We intentionally separated hematology and oncology into two volumes, thereby allowing readers to consider and purchase either *Hematology of Infancy and Childhood* or *Oncology of Infancy and Childhood*. To accomplish the task of creating an oncology volume de novo, we invited our colleagues Tom Look and David Fisher to join as editors.

By branding the eighth edition with a unified title, the editors have declared the experiment of the seventh edition a success. We believe the expanded scope of the textbook has been well received by readers and more accurately reflects the state of the entire field of pediatric hematology and oncology. The rather artificial distinction between hematology and oncology pained us as editors. Where would we now place leukemia if restricted to one or the other volume? Don't the bone marrow failure syndromes that often evolve to frank malignancy constitute an important bridge between the two areas? As many trainees and practitioners in pediatric hematology and oncology devote a majority of their time to oncology, the need to bring a unified package forward was clear.

We hope that the current form of *Hematology and Oncology of Infancy and Childhood* captures the enormous progress in our understanding and management of non-malignant and malignant conditions in pediatrics. The last two decades have been revolutionary in terms of discovery. The impact of molecular biology, human genetics, immunology, and chemistry on pediatric hematology and oncology, as on all medicine, has been extraordinary. It is now commonplace to anticipate that the entire genome of every child with cancer or a blood disorder will be determined going forward based on the expectation that a full genetic profile will lead to personalized and more effective treatment. To encompass areas of broad relevance that were not covered previously, we have added new chapters. Mel Greaves, a distinguished leader in childhood leukemia, has graced our text with his views on the origin and evolution of cancer, indeed retracing some of Darwin's logic for us. Because informatics has become a critical component of all genomic efforts, we solicited a new chapter on informatics that has been written by Sam Volchenboum. Given the increasing excitement and relevance of epigenetics to childhood cancer, we asked two experts in this area, Charles Roberts and Alex Kentsis, to provide a new contribution on this topic. As always, we hope that readers will provide frank and constructive feedback on this edition. To do justice to the entire field of pediatric hematology and oncology may be a near impossible task. The editors have given their best efforts on behalf of the cause. The readers are our judges.

The eighth edition has truly been a team effort. I cannot thank the other editors enough for their dedication to this project. We are most grateful to the authors of each chapter for their contributions. The editorial staff at Elsevier kept us on course, even when it seemed that we would not make our deadlines. We appreciate everything they have done and more.

It is an honor to be in the field of pediatric hematology and oncology.

Stuart H. Orkin, MD

ACRONYMS

A

A2: annexin 2
AA: arachidonic acid
AABB: American Association of Blood Banks
AAE: acquired angioedema
AAIR: age-adjusted incidence rate
AAP: American Academy of Pediatrics
AAV: adeno-associated virus
ABC: ATP-binding cassette transporter superfamily
ABCB7: ATP-binding cassette subfamily B member 7, mitochondrial
ABL: Abelson kinase, Abelson gene product
ABO: ABO(H) blood group system
ABP: actin-binding protein
ABP-1: actin-binding protein-1
ACO1: aconitase 1
ACS: acute chest syndrome
ACE: angiotensin-converting enzyme
ACIP: Advisory Committee on Immunization Practices
ACTH: adrenocorticotropic hormone, adrenocorticotropin
AD: anauxetic dysplasia; autosomal dominant
ADA: adenosine deaminase
ADAD: ADA deficiency
ADC: apparent diffusion coefficient
ADCC: antibody-dependent cellular cytotoxicity; antibody-dependent cell-mediated cytotoxicity
AdoCbl: adenosylcobalamin, 5′-deoxyadenosylcobalamin
AdoHcy: *S*-adenosylhomocysteine
AdoMet: *S*-adenosylmethionine
ADP: adenosine diphosphate; ALA-D deficiency porphyria; antibody-dependent phagocytosis
ADPase: adenosine diphosphatase
AE1: anion exchange protein 1 (band 3 protein of the red cell membrane)
AFP: α-fetoprotein
AGLT: acidified glycerol lysis test
AGM: aorta-gonad-mesonephros
aGVHD: acute graft-versus-host disease
AH50: alternative pathway complement hemolysis 50%
AHA: acute hemolytic anemia
AHG: antihuman globulin
AHSP: α-hemoglobin–stabilizing protein
aHUS: atypical hemolytic uremic syndrome
AICAR: amino-4-imidazolecarboxamide ribonucleotide
AICD: activation-induced cell death
AICDA: activation-induced cytidine deaminase (gene)
AID: activation-induced cytidine deaminase, activation-induced deaminase
AIDS: acquired immunodeficiency virus
AIHA: autoimmune hemolytic anemia
AIN: autoimmune neutropenia
AIP: acute intermittent porphyria
AIRE: autoimmune regulator
AIS: arterial ischemic stroke
AK: adenylate kinase
AK2: adenylate kinase 2
ALA: δ-aminolevulinic acid
ALA-D: δ-aminolevulinic acid dehydratase
ALA-S: δ-aminolevulinic acid synthase
ALCL: anaplastic large-cell lymphoma
ALD: adrenoleukodystrophy
ALDH: aldehyde dehydrogenase
ALG: antilymphocyte globulin
ALK: anaplastic lymphoma kinase
ALL: acute lymphoblastic leukemia; acute lymphocytic leukemia; acute myeloblastic leukemia; acute myeloid leukemia
ALM: activation loop mutations
ALPS: autoimmune lymphoproliferative syndrome
AMKL: acute megakaryoblastic leukemia
AML: acute myelogenous leukemia; acute myeloid leukemia
AMT: amegakaryocytic thrombocytopenia
ANC: absolute neutrophil count
ANCA: antineutrophil cytoplasmic antibody
α_2-AP: α_2-antiplasmin
AP3B1: adaptor protein 3 complex β3A subunit
APA: antiphospholipid antibody
APC: activated protein C, adenomatous polyposis coli, antigen-presenting cell
APCC: activated prothrombin complex concentrate
APECED: autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy
APHON: Association of Pediatric Hematology/Oncology Nurses
APL: acute promyelocytic leukemia
APLA: antiphospholipid antibody
APOL1: apolipoprotein L1
APRCA: acquired pure red cell aplasia
APRIL: α-proliferation–inducing ligand
APS-1: autoimmune polyglandular syndrome type 1
APTT: activated partial thromboplastin time
AQP1: aquaporin-1
AR: autosomal recessive; androgen receptor
Ara-CMP: arabinosylcytosine 5′ monophosphate
ARC: Australia Research Council
ARF: alternate reading frame
ARSB: arylsulfatase B
ARTUS: amegakaryocytic thrombocytopenia with radio-ulnar synostosis
ASA: arylsulfatase A
ASBMT: American Society for Blood and Marrow Transplantation
ASCO: American Society of Clinical Oncology
ASCT: autologous stem cell transplant
ASH: American Society of Hematology

ASL: arterial spin labeling
ASM: acid sphingomyelinase; aggressive systemic mastocytosis
AST: aspartate aminotransferase
AT: antithrombin; ataxia-telangiectasia
ATG: antithymocyte globulin
ATLS: acute tumor lysis syndrome
ATM: ataxia-telangiectasia mutated
ATOX1: antioxidant 1 copper chaperone
ATP: adenosine triphosphate
ATPase: adenosine triphosphatase
ATP7A: ATPase, Cu^{2+} transporting, alpha polypeptide
ATRA: all-*trans*-retinoic-acid
ATRUS: amegakaryocytic thrombocytopenia with radioulnar synostosis
AUC: area under the plasma concentration vs. time curve
AVN: avascular necrosis
AVWS: acquired von Willebrand syndrome
AZT: zidovudine

B

β-LCR: β-locus control region
BACT: BCNU (carmustine)/Ara-C (cytarabine)/cyclophosphamide/6-thioguanine
BACH1: BTB and CNC homology 1
BAEP: brainstem auditory evoked potential
BAER: brainstem auditory evoked responses
BAF: BRG1-associated factor
BAFF: B-cell–activating factor
BAFFR: BAFF receptor
BAL: bronchoalveolar lavage
BAL: British anti-Lewisite
B-ALL: B-cell acute lymphoblastic leukemia; B-precursor ALL
BCAM: basal cell adhesion molecule
BCG: bacille Calmette-Guérin
BCL10: B-cell lymphoma 10
BCNU: carmustine
BCR: B-cell receptor; breakpoint cluster region
BDNF: brain-derived neutrotrophic factor
BEAM: BCNU (carmustine)/etoposide/Ara-C (cytarabine)/melphalan
BET: bromodomain and extraterminal
BFU-E: burst-forming unit–erythrocyte
BFU-Meg: burst-forming unit–megakaryocyte
bHLH: basic helix-loop-helix
BiPAP: bilevel positive airway pressure
BIRC4: baculoviral IAP repeat-containing 4
BiTEs: bispecific T-cell engagers
BLM: Bloom syndrome, RecQ helicase-like
BLNK: B-cell linker protein
BM: bone marrow
BMD: bone mineral density
BMF: bone marrow failure
BMI: body mass index
BMP: bone morphogenetic protein
BMT: bone marrow transplantation
BMT-MA: bone marrow transplantation–associated microangiopathy
BPGM: 2,3-bisphosphoglycerate mutase
BPI: bactericidal/permeability-increasing protein
BRB: blood-retinal barrier; blood-eye barrier
BRCA1: breast cancer 1, early onset
BrdU: bromodeoxyuridine
BrOb: bronchiolitis obliterans
BRM: biologic response modifier
BSAP: B-cell–specific activator protein
BSP: bromsulfophthalein
BSS: Bernard-Soulier syndrome
BT: bleeding time
Btk: Bruton tyrosine kinase
BU: Bethesda units, busulfan
BUGT: bilirubin UDP-glucuronyltransferase
BWS: Beckwith-Wiedemann syndrome
bZIP: basic region–leucine zipper domain

C

C282Y: cysteine 282 to tyrosine
C: constant
CAD: cold agglutinin disease
CADP: collagen/adenosine diphosphate
CAFC: cobblestone area–forming cell
CAIV: carbonic anhydrase IV
CALGB: Cancer and Leukemia Group B
CaM: calmodulin
CAM: complementary and alternative medicine
cAMP: cyclic adenosine monophosphate
CAMT: congenital amegakaryocytic thrombocytopenia
CaNaEDTA: calcium disodium-ethylenediaminetetraacetic acid
CAR: Central African Republic; chimeric antigen receptor
CARD: caspase recruitment domain family member
CASP: caspase
CAT: calibrated automated thrombography
CB: cord blood
CBB: cord blood bank
C4bBP: C4b-binding protein
CBF: core-binding factor
CBP: cyclophosphamide/BCNU (carmustine)/cisplatin
CBV: cyclophosphamide/BCNU (carmustine)/VP-16 (etoposide)
CCG: Children's Cancer Study Group
CCI: corrected count increment
CCSK: clear cell sarcoma of the kidney
CCyR: complete cytogenetic response
CD: cluster of differentiation
CD3D, CD3E, CD3G, CD3Z, CD3: δ, ε, γ, chains, respectively
CD40L: CD40 ligand
CDA: congenital dyserythropoietic anemia
CDA: cytidine deaminase
CDC: complement-dependent cytotoxicity
Cdc42: cell division control protein 42
CDK: cyclin-dependent kinase
CDP: CCAAT displacement protein; cytidine diphosphate
CDR3: complementarity-determining region 3
C/EBP: CCAAT/enhancer-binding protein α
CEP: congenital erythropoietic porphyria

CEPI: collagen/epinephrine
CESD: cholesteryl ester storage disease
CFC: colony-forming cell
CFC-Eo: eosinophil colony-forming cell
CFU-C: colony-forming unit in culture
CFU-E: colony-forming unit–erythrocyte
CFU-Eo: colony-forming unit–eosinophil
CFU-GEMM: colony-forming unit–multipotent (granulocyte, erythrocyte, macrophage, megakaryocyte)
CFU-GM: colony-forming unit–granulocyte-macrophage
CFU-Meg: colony-forming unit–megakaryocyte
CFU-S: colony-forming unit–spleen
CGD: chronic granulomatous disease
CGH: comparative genomic hybridization
cGMP: current good manufacturing practice; cyclic guanosine monophosphate
CGP: circulatory granulocyte pool
cGVHD: chronic graft-versus-disease
CH: calponin homology domain
CHBA: congenital Heinz body hemolytic anemia
CHF: congestive heart failure
CH50: classical pathway complement hemolysis 50%
CHH: cartilage-hair hypoplasia
CHO: Chinese hamster ovary
CHL: classic Hodgkin lymphoma
CHOP: **c**yclophosphamide, **h**ydroxydaunorubicin, **o**ncovin, and **p**redsinone or **p**rednisolone
CHR: complete hematologic response
CHr: cellular hemoglobin of the reticulocyte
CHS: Chédiak-Higashi syndrome
CIBMTR: Center for International Blood and Marrow Transplant Research
CIK: cytokine-induced killer cell
CIITA: class II *trans*-activator
C1-INH: C1 esterase inhibitor
CI: confidence interval
CIS: cytokine-inducible SH2-containing protein
Cl^-: chloride anion
CLABSI: central line–associated bloodstream infection
CLC: Charcot-Leyden crystal
ClC: chloride channel (may be followed by -7 or other number)
CLIA: Clinical Laboratory Improvement Amendment
CLL: chronic lymphocytic leukemia
CLN-1: neuronal ceroid lipofuscinosis type 1
CLP: common lymphoid progenitor
CMC: chronic mucocutaneous candidiasis
CML: chronic myelocytic leukemia; chronic myelogenous leukemia
CMN: cellular congenital mesoblastic nephroma
cMOAT: canalicular multispecific organic anion transporter
CMP: common myeloid progenitor; cytidine monophosphate
CMV: cytomegalovirus
CN: Crigler-Najjar syndrome, type I (CNI) or type II (CNII); cyanide; cystic nephroma
CNB: core needle biopsy
CNCbl: cyanocobalamin
CNS: central nervous system
CNSHA: congenital nonspherocytic hemolytic anemia
CNTF: ciliary neurotrophic factor
CNV: copy number variation
CO: carbon monoxide
CO_2: carbon dioxide
CoA: coenzyme A
COG: Children's Oncology Group
COJEC: cisplatin, vincristine, carboplatin, etoposide, and cyclophosphamide
COL1A1: collagen, type I, α1
COPA: cancer outlier profile analysis
COX-1: cyclooxygenase-1
COX-2: cyclooxygenase-2
CP: connecting peptides
CPAP: continuous positive airway pressure
CPD: citrate-phosphate-dextrose
CPDA-1: citrate-phosphate-dextrose-adenosine
CPDN: cystic, partially differentiated nephroblastoma
CPO: coproporphyrinogen oxidase
CPP: choroid plexus papillomas
CR: complete remission
CR1: complement receptor 1
CRAC: calcium release–activated calcium
CREG: cross-reactive group
CRF: chronic renal failure
CRHR1: corticotropin-releasing hormone receptor 1
CRIg: complement receptor of the immunoglobulin superfamily
CRISPR: clustered regularly interspaced short palindromic repeats
CRLF2: cytokine receptor-like factor 2
CRM: cross-reacting material
CRP: cross-reactive protein; C-reactive protein
CRT: catheter-related thrombosis
CRX: cone-rod homeobox
CSA: congenital sideroblastic anemia
CSF: cerebrospinal fluid; colony-stimulating factor
c-SMAC: central supramolecular activation cluster
CSR: class switch recombination
CSC: cancer stem cells
CSSCD: Cooperative Study of Sickle Cell Disease
CSVT: cerebral sinovenous thrombosis
CT: closure time; computed tomography
CTCL: cutaneous T-cell leukemia
CIITA: MHC class II transactivator
CT-1: cardiotropin-1
CTD: C-terminal domain
CTL: cytotoxic T lymphocyte
CTLA-4: cytotoxic T-lymphocyte antigen 4
CTP: cytidine triphosphate
CTR1: copper transporter 1
Cu-ATPase: adenosine triphosphatase transmembrane copper transporter
CVID: common variable immunodeficiency
CVL: central venous line
CVS: chorionic villus sampling
CXCR4: CXC chemokine receptor 4
CXR: chest radiography
CY: cyclophosphamide
CYP: cytochrome P

D

D: diversity
DA: diffuse anaplasia
DAF: decay accelerating factor
DAG: diacylglycerol
DAMP: damage-associated molecular pattern
DAP: DNAx activating protein (au query; set OK?)
DAT: direct antibody test, direct antiglobulin test
dATP: deoxyadenosine triphosphatase
DBA: Diamond-Blackfan anemia
DC: dyskeratosis congenita
DCC: delayed cord clamping
DCE: downstream core element
DCK: deoxycytidine kinase
DCLRE1C: DNA cross-link repair enzyme 1C
DCRLRE1C: DNA cross-link repair enzyme 1C
DCT1: divalent cation transporter 1
DDAVP: 1-deamino-8-D-arginine vasopressin
DEB: diepoxybutane
deoxy-Hb: deoxygenated hemoglobin
DFMO: a-difluoromethylornithine
DFS: dermatofibrosarcoma; disease-free survival
DGS: DiGeorge syndrome
dGTP: deoxyguanosine triphosphatase
DHAP: dihydroxyacetone phosphate
DHF: dengue hemorrhagic fever; 7,8-dihydrofolate
DHFR: dihydrofolate reductase
DHR 123: dihydroxyrhodamine 123
DIC: disseminated intravascular coagulation
DIDMOAD: diabetes insipidus, diabetes mellitus, optic atrophy, and deafness
DIDS: 4,4′-diisothiocyanostilbene-2,2′-disulfonate (anion channel inhibitor)
DIIHA: drug-induced immune hemolytic anemia
DJS: Dubin-Johnson syndrome
DLI: donor lymphocyte infusion
DLBCL: diffuse large B-cell lymphoma
DLT: dose-limiting toxicity
DMS: demarcation membrane system
DMSO: dimethyl sulfoxide
DMT1: divalent metal transporter 1
DNA: deoxyribonucleic acid
DNA-PKcs: DNA-dependent protein kinase catalytic subunit
DNET: dysembryoplastic neuroepithelial tumors
DNM3TA: DNA methyltransferase 3A
DNM3TB: DNA methyl transferase 3B
DNTs: double-negative T cells
DOCK8: dedicator of cytokinesis 8
DLI: donor lymphocyte infusion
DOPA: 3,4-dihydroxyphenylalanine
DOT1L: Histone-*lysine*-N-methyltransferase, H3 *lysine*-79–specific
DP: double-positive
2,3-DPG: 2,3-diphosphoglycerate
DPT: diphtheria and tetanus toxoids and pertussis
DRESS: drug rash with eosinophilia and systemic symptoms (syndrome)
dRTA: distal renal tubular acidosis
DRVVT: dilute Russell viper venom time
DS: Down syndrome
DS-AMKL: Down syndrome–acute megakaryoblastic leukemia
DSRCT: desmoplastic small round blue cell tumors
DSS: dengue shock syndrome
DS-TMD: Down syndrome–transient myeloproliferative disorder
DTB: ditaurobilirubin
DTI: Diffusion tensor imaging
dTMP: thymidylate (deoxythymidine monophosphate)
DTS: dense tubular system
DVI: partial D category VI phenotype
DVT: deep venous thrombosis
DWI: diffusion-weighted imaging

E

EA: early antigen
EBA140: *Plasmodium falciparum* erythrocyte binding antigen 140
EBMT: European Group for Blood and Marrow Transplantation
EBP: elastin-binding protein
EBRT: external beam radiation therapy
EBV: Epstein-Barr virus
EC: Enzyme Commission
ECLT: euglobulin clot lysis time
ECMO: extracorporeal membrane oxygenation
EDA-ID: anhidrotic ectodermal dysplasia with immunodeficiency
EDAS: encephaloduroarteriosynangiosis
EDAMS: encephaloduroarteriomyosynangiosis
EDS: Ehlers-Danlos syndrome
EDTA: ethylenediaminetetraacetic acid
EFS: event-free survival
EGA: estimated gestational age
EGF: epidermal growth factor
EGFR: epidermal growth factor receptor
EHEC: enterohemorrhagic *Escherichia coli*
EKLF: erythroid Krüppel-like factor
ELISA: enzyme-linked immunoabsorbent assay
EM: extramedullary
eNOS: endothelial nitric oxide synthase
ENU: *N*-ethyl-*N*-nitrosourea
EPCR: endothelial cell protein C receptor
EPEC: enteropathogenic *Escherichia coli*
EPO: erythropoietin
EpoR: erythropoietin receptor
EPP: erythropoietic protoporphyria
EPR: electron paramagnetic resonance
ER: endoplasmic reticulum; estrogen receptor
ERGIC-53: endoplasmic reticulum–Golgi intermediate compartment, 53 kilodalton protein
ERT: enzyme replacement therapy
ES: embryonic stem
ESC: embryonic stem cell
ESL-1: E-selectin ligand-1
ESRD: end-stage renal disease
ET: essential thrombocythemia
ETANTRs: embryonal tumors with abundant neuropile and true rosettes
EV: epidermodysplasia verruciformis

EVER: epidermodysplasia verruciformis
EZH2: enhancer of zeste 2

F

FA: Fanconi anemia; focal anaplasia
FAAP: Fanconi anemia–associated protein
FAB: French-American-British (staging)
Fab: antigen-binding fragment
FACS: fluorescence-activated cell sorting
FACT: Foundation for the Accreditation of Cell Therapy
FAD: flavin adenine dinucleotide
FADD: Fas-associated via death domain
FAH: fumarylacetoacetate hydrolase
FAICAR: formamido-4-imidazolecarboxamide ribonucleotide
FAK: focal adhesion kinase
FASLG: FAS ligand
FBN: fibronectin
FBXL5: F-box and leucine-rich repeat protein 5
FCP: F-cell production (locus)
FcR: Fc receptor
FcγR: IgG Fc receptor
FDA: Food and Drug Administration
FDC: follicular dendritic cell
FDG-PET: fluorine 18–labeled deoxyglucose positron emission tomography
FDP: familial platelet deficiency; fibrin(ogen) degradation product; fructose 6-diphosphate
FECH: ferrochelatase
FEIBA: factor eight inhibitor–bypassing activity
FEP: free erythrocyte protoporphyrin
Fe-SIH: ferric salicylaldehyde-isonicotinyl-hydrazone
FFP: fresh-frozen plasma
FGAR: formylglycinamide ribonucleotide
FGF: fibroblast growth factor
fH: factor H
FHL: familial hemophagocytic lymphohistiocytosis
fI: factor I
FIGlu: formiminoglutamic acid
FISH: fluorescence in situ hybridization
FKBP: FK-binding proteins
FL: ligand for the Flks/Flt3 receptor
FLAER: fluorescent aerolysin
FLAIR: fluid-attenuated inversion recovery
FLIP: FLICE-like inhibitory protein
FLT3: fms-related tyrosine kinase 3
FMH: fetomaternal hemorrhage
FN: fever and neutropenia
FNA: fine needle aspiration
FOG-1: friend of GATA-1
FOX: forkhead box transcription factor
FPA: fibrinopeptide A
FPB: fibrinopeptide A
F-PCT: familial porphyria cutanea tarda
FPN1: ferroportin 1
FRAP: fluorescence recovery after photobleaching
FSGS: focal sclerosing glomerulosclerosis
FTCD: formiminotransferase-cyclodeaminase
5-FU: 5-fluorouracil
FUO: fever of unknown origin

G

γc: cytokine receptor common gamma chain
G6PD: glucose-6-phosphate dehydrogenase
GABA: γ-aminobutyric acid
GAG: glycosaminoglycan
β-gal: β-d-galactosidase
GalNAc-T: *N*-acetylgalactosaminyltransferase
GALNS: *N*-acetylgalactosamine-6-sulfatase
GAP: GTPase-activating protein
GAR: glycinamide ribonucleotide
GAS: IFN-γ–activated sequence
GAT: granulocyte agglutination test
GBS: Guillain-Barré syndrome
GC: germinal center; glucocorticoids
GCase: acid β-glucosidase; glucocerebrosidase (i.e, the Gaucher disease enzyme)
G-CSF: granulocyte colony-stimulating factor
G-CSFR: granulocyte colony-stimulating factor receptor
GDF: growth and differentiation factor
GDF15: growth differentiation factor 15
GDP: guanosine diphosphate
GEMMs: genetically engineered mouse models
GFR: glomerular filtration rate
GH: growth hormone
GI: gastrointestinal
GIF: gastric intrinsic factor
GIFT: granulocyte immunofluorescence test
GIST: gastrointestinal stromal tumors
GITMO: Gruppo Italiano Trapianti di Midollo Osseo
GlcNAc: *N*-acetylglucosamine
GLRX5: glutaredoxin 5
Glu-Plg: glutamic acid plasminogen
GluR1: glutamate receptor type 1
GM2A: GM2 activator protein
GM-CSF: granulocyte-macrophage colony-stimulating factor
GMP: granulocyte-monocyte precursor, guanosine monophosphate; granulocytic-monocytic–restricted progenitors
GMTZ: gemtuzumab ozogamicin
GNPT: UDP-*N*-acetylglucosamine:lysosomal-enzyme *N*-acetylglucosamine-1-phosphotransferase
GnRH: gonadotropin-releasing hormone
GP: glycoprotein
GPA: glycophorin A
GPB: glycophorin B
GPC: glycophorin C
GPCR: G protein–coupled receptor
GPD: glycophorin D
G3PD: glyceraldehyde-3-phosphate dehydrogenase
G6PD: glucose-6-phosphate dehydrogenase
GPE: glycophorin E
GPI: glucose phosphate isomerase, glycosylphosphatidylinositol
GPIb: glycoprotein Ib
GPS: gray platelet syndrome
GRF: guanine nucleotide–releasing factor
GRO: growth-regulated oncogene
GS: Gilbert syndrome; Griscelli syndrome
GS2: Griscelli syndrome type 2

GSCbl: glutathionylcobalamin
GSH: reduced glutathione, γ-secretase inhibitor
GSK3: glycogen synthase kinase 3
GSL: glycosphingolipid
GSSG: oxidized glutathione
GSHPX: glutathione peroxidase
GST: glutathione-*S*-transferase
GT: Glanzmann thrombasthenia
GTP: guanosine triphosphate; guanosine nucleotide phosphate
GTPase: guanosine triphosphatase
GV: gemcitabine and vinorelbine
GVHD: graft-versus-host disease
GVL: graft versus leukemia

H

H3K27: lysine 27 of histone 3
H3K79: lysine 79 of histone 3
H63D: histidine 63 to aspartic acid
H^+: hydrogen cation
HAART: highly active antiretroviral therapy
HABA: 2(4′-hydroxyazobenzene) benzoic acid
HAE: hereditary angioedema
HAMP: hepcidin antimicrobial peptide
Hb: hemoglobin
HB: Heinz body
HbA: adult hemoglobin
HbF: fetal hemoglobin
HBV: hepatitis B virus
HC: homocysteine; haptocorrin (also called transcobalamin I or R binder)
4-HC: 4-hydroperoxycyclophosphamide
HCP: hereditary coproporphyria, hematopoietic cell phosphatase
HCV: hepatitis C virus
HD: Hodgkin disease; homodimerization
HDAC: Histone deacetylase
HDL: high-density lipoprotein
HDN: hemolytic disease of the fetus and newborn; hemorrhagic disease of the newborn
HDW: hemoglobin distribution width
HE: hereditary elliptocytosis
HELLP: hemolytic anemia, elevated liver enzymes, low platelet count
HEMPAS: hereditary erythroblastic multinuclearity with a positive acidified serum lysis test
HEP: hepatoerythropoietic porphyria
HES: Hairy and Enhancer of Split, hypereosinophilic syndrome
HETE: 15(*S*)-hydroxyeicosatetraenoic acid
Hex-A: hexosaminidase A
Hex-B: hexosaminidase B
HFE: HLA-linked human hemochromatosis protein
HGF: hematopoietic growth factor; hepatocyte growth factor
HGFR: hematopoietic growth factor receptor
HHS: Hoyeraal-Hreidarsson syndrome
HHV-6: human herpesvirus 6
HHV-8: human herpesvirus 8
HiB: *Haemophilus influenzae* type B
HIDA: hepatobiliary iminodiacetic acid
HIES: hyperimmunoglobulin E syndrome (hyper-IgE syndrome)
HIF: hypoxia-inducible factor
HIF-1: hypoxia-inducible factor 1
HIM: hyper-IgM syndrome
HIT: heparin-induced thrombocytopenia
HITTS: HIT with thrombosis syndrome
HIV: human immunodeficiency virus
HJV: hemojuvelin
HK: hexokinase
HLA: human leukocyte antigen
HLH: hemophagocytic lymphohistiocytosis
HMB: hydroxymethylbilane
HMGB1: high–molecular group box 1 protein
HMP: hexose monophosphate
HMPV: human metapneumovirus
HMS: hyperreactive malarial splenomegaly
HMWK: high-molecular-weight kininogen
HNE: hydroxynonenal
hnRNA: heterogeneous nuclear RNA
HO: heme oxygenase
HOCl: hypchlorous acid
H_2O_2: hydrogen peroxide
H_2OCbl: aquocobalamin
holo-HC: holohaptocorrin
holo-TC: holotranscobalamin
HOX: homeobox transcription factor
HPA-1a: human platelet antigen 1a
HPC: hematopoietic progenitor cell
HPCHA: high-phosphatidylcholine hemolytic anemia
HPFH: hereditary persistence of fetal hemoglobin
HPLC: high-performance liquid chromatography; high-pressure liquid chromatography
HPP: hereditary pyropoikilocytosis
HPP-CFCs: high–proliferative potential colony-forming cells
HPRT: hypoxanthine phosphoribosyltransferase
HPS: Hermansky-Pudlak syndrome
HPV: human papillomavirus
HR: homologous recombination
HRE: hypoxia response element
HRI: heme-regulated inhibitor kinase
HRM: heme regulatory motif
HRQoL: Health-related quality of life
HS: hereditary spherocytosis; hypersensitivity site
HSC: hematopoietic stem cell
HSCT: hematopoietic stem cell transplantation
HSP: heat shock protein; Henoch-Schönlein purpura
HSt: hereditary stomatocytosis
HSV: herpes simplex virus
5-HT: *5′*-hydroxytryptamine (serotonin)
HTLV: human T-cell leukemia/lymphoma virus; human T-cell lymphotropic virus
HUS: hemolytic uremic syndrome
HUSOFT: Hydroxyurea Safety and Organ Toxicity
HUVEC: human umbilical vein endothelial cell

I

IAP: integrin-associated protein or CD47
IAS: ischemic arterial stroke
IBMFS: inherited bone marrow failure syndrome

IBMTR: International Bone Marrow Transplant Registry
ICAM: intercellular adhesion molecule
ICE: ifosfamide, carboplatin, and etoposide
ICD-9: International Classification of Diseases, 9th revision
ICF: immunodeficiency-centromeric instability facial anomalies
ICG: indocyanine green
ICH: intracranial hemorrhage
ICN: intracellular domain of Notch
ICOS: inducible costimulator; inducible T-cell costimulator
ICOSL: inducible costimulator ligand
IDO: indolamine 2,3-dioxygenase
IDS: iduronate 2-sulfatase
IDUA: α-l-iduronidase
IE: ineffective erythropoiesis
IEF: isoelectric focusing
IF: intrinsic factor
IFAR: International Fanconi Anemia Registry
IFI: invasive fungal infection
IFN: interferon
IFN-α: interferon-α
IFN-γ: interferon-γ
IFNGR: interferon γ receptor
IFRT: involved-field radiotherapy
IFS: infantile sarcoma
IgA: immunoglobulin A
IGAD: IgA deficiency
IGF-1: insulin-like growth factor 1
IGFBP: insulin-like growth factor binding protein
IgE: immunoglobulin E
IgG: immunoglobulin G
IgM: immunoglobulin M
IGGSD: IgG subclass deficiency
IHC: immunohistochemistry
IκB: inhibitor of NF-κB
IKBA: inhibitor of NF x-B α chain
IKK: IκB kinase
IL: interleukin
IL-1RA: IL-1 receptor antagonist
IL-2: interleukin-2 (also IL-1, IL-3, IL-4, etc.)
IL2RG: interleukin-2 receptor gamma (IL-2R γ)
IL-6R: interleukin-6 receptor
IL-“X”R: IL-“X” receptor
ILNR: intralobar nephrogenic rests
IMP: inosine 5′-monophosphate; intramembrane particle
IMRT: intensity-modulated radiation therapy
IMT: inflammatory myofibroblastic tumor
iNKT: invariant natural killer T cell
iNOS: inducible nitric oxide synthase
INPC: International Neuroblastoma Pathology Classification
INR: international normalized ratio
INRG: International Neuroblastoma Risk Group
INSS: International Neuroblastoma Staging System
IRS: Intergroup Rhabdomyosarcoma Study
IP: isoprostenoid
IP_3: inositol 1,4,5-triphosphate
IPEX: immune dysregulation, polyendocrinopathy, enteropathy, X-linked (syndrome)
IPH: idiopathic pulmonary hemosiderosis
IPT: intraperitoneal fetal transfusion
IRAG: IP_3 receptor–associated cGMP
IRAK-4: interleukin-1 receptor–associated kinase 4
IRE: iron response element, iron responsive element
IREG1: iron-regulated transporter
IRF: interferon regulatory factor
IRIDA: iron-refractory iron deficiency anemia
IRP: IRE-binding protein, iron regulatory protein
IRSS: International Retinoblastoma Staging System
ISBT: International Society for Blood Transfusion
ISC: irreversibly sickled cell
ISH: in situ hybridization
ISHAGE: International Society for Hematotherapy and Graft Engineering
ISI: International Sensitivity Index
ISM: indolent systemic mastocystosis
ISP: intermediate single positive
ISRE: interferon-stimulated response element
IST: immunosuppressive therapy
ISTH: International Society on Thrombosis and Hemostasis
ITAM: immunoreceptor tyrosine–based activation motif, immunoreceptor tyrosine activation motif
ITCH: itchy E3 ubiquitin protein ligase
ITD: internal tandem duplication
ITIM: immunoreceptor tyrosine–based inhibitory motif, immunoreceptor tyrosine activation motif
ITP: immune thrombocytopenia purpura
ITK: IL-2 inducible tyrosine kinase
iTreg: inducible Treg
IVIG: intravenous immune serum globulin, intravenous immunoglobulin
IVS: intervening sequence (intron)
IVT: intravascular transfusion

J

J: joining
JAK: Janus kinase
JAK-STAT: Janus kinase–signal transducer and activator of transcription
JAM-1: junctional adhesion molecule 1
JCML: juvenile chronic myelomonocytic leukemia
JIA: juvenile idiopathic arthritis
JME: juxtamembrane expansion
JMML: juvenile myelomonocytic leukemia

K

kb: kilobase
KCC: K^+-Cl^- cotransporter
K_d: dissociation constant
KD: Kostmann’s disease, kyphomelic dysplasia
KEYY: lysine–glutamic acid–tyrosine-tyrosine
KIF1B: kinesin family member 1B
KIR: killer cell immunoglobulin-like receptor
KL: Klotho (gene)
K_m: Michaelis constant
KRAS: v-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog
KTLS: c-Kit$^+$, Thy-1^{lo}, Lin$^-$, Sca-1$^+$ cell

KLF4: Krüppel-like factor 4
KLH: keyhole limpet hemocyanic
KSS: Kearns-Sayre syndrome

L

LA: lupus anticoagulant
LAD I: leukocyte adhesion deficiency type I
LAD II: leukocyte adhesion deficiency type II
LAD III: leukocyte adhesion deficiency type III
LAL: lysosomal acid lipase
LAMP-3: lysosome-associated membrane protein 3
LASD: lysosomal autophagy system disease
LAP: localized aggressive periodontitis; leukocyte alkaline phosphatase
LAT: linker for activation of T cells
LCAT: lecithin-cholesterol acyltransferase
Lck: lymphocyte-specific protein tyrosine kinase
LCL: large cell lymphoma
LCR: locus control region
LDH: lactate dehydrogenase
LDHL: lymphocyte-depleted Hodgkin lymphoma
LD-RIPA: low-dose ristocetin-induced platelet aggregation
LDL: low-density lipoprotein
LEF-1: lymphoid enhancer–binding factor 1
LELY: low-expression allele Lyon
LEPRA: low-expression allele Prague
LFA-3: lymphocyte function antigen 3
LFS: Li-Fraumeni syndrome
LGL: large granular lymphocyte leukemia
LHRF: luteinizing hormone–releasing factor
LIC: leukemia-initiating cells
LIF: leukemia inhibitory factor
LIFR: leukemia inhibitory factor receptor
LIG4: DNA ligase IV
LIR: leukocyte immunoglobulin-like receptor
LJP: localized juvenile periodontitis
LL: lymphoblastic lymphoma
LMIC: low- and middle-income countries
LMO2: LIM domain only 2 (rhombotin-like 1)
LMWH: low-molecular-weight heparin
LMWK: low-molecular-weight kininogen
LNR: Lin12-NOTCH repeats
LOH: loss of heterozygosity
LPS: lipopolysaccharide
LRHL: lymphocyte-rich Hodgkin lymphoma
LRP: lipoprotein receptor–related protein
LRRC8: leucine-rich repeat–containing 8
LSD: lysosomal storage disease
LSP1: lymphocyte-specific protein 1
LT: leukotriene
LTB$_4$: leukotriene B$_4$
LTC-IC: long-term culture–initiating cell
LTR: long terminal repeat
LTR-HSCs: long-term–reconstituting hematopoietic stem cells
LW: Landsteiner-Weiner glycoprotein
Lyso-PC: lysophosphatidylcholine
Lys-Plg: lysine plasminogen
LYST: lysosomal trafficking regulator

M

mAbs: monoclonal antibodies
MAGE: melanoma antigen-encoding gene
MAGT1: magnesium transporter protein 1
MAGUK: membrane-associated guanylate kinase
MAIT: mucosa-associated invariant T
MALT1: mucosa-associated lymphoid tissue lymphoma translocation gene 1
MAP: mitogen-activated protein
MAPK: mitogen-activated protein kinase
MARCKS: myristoylated alanine-rich C kinase substrate
MAS: macrophage activation syndrome
MASP: MBL-associated serine protease
MASCC: Multinational Association of Supportive Care in Cancer
Mb: myoglobin
MBD: membrane-binding domain
MBL: mannose-binding lectin
MBP: major basic protein
MCH: mean corpuscular hemoglobin
MCHL: mixed-cellularity Hodgkin lymphoma
MCHC: mean corpuscular hemoglobin concentration
MCL: mast cell leukemia
MCM4: mini-chromosome maintenance-deficient 4
MCP: membrane cofactor protein
MCP-1: monocyte chemotactic protein 1
M-CSF: macrophage colony-stimulating factor
MCV: mean cell volume; mean corpuscular volume
MCV4: meningococcal conjugate vaccine
MCyR: major cytogenetic response
MDCK: Madin-Darby canine kidney (cells)
MDM2: murine double minute 2
MDS: myelodysplastic syndrome
MDWH: metaphyseal dysplasia without hypotrichosis
MeCbl: methylcobalamin
MEK: MAPK kinase
MELAS: mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes
MEN1: multiple endocrine neoplasia type I
MEP: megakaryocyte, erythroid, and basophil (lineage); megakaryocyte/erythroid precursor
met-Hb: methemoglobin
5-methyl-THF: 5-methyltetrahydrofolate
α_2-MG: α_2-macroglobulin
MGF: myelomonocytic growth factor
MGP: marginating granulocyte pool
MGSA: melanoma growth stimulatory activity
mHA: minor histocompatibility antigen
MHA: May-Hegglin anomaly
MHC: major histocompatibility complex
MIBG: metaiodobenzylguanidine
micro-PET: micro–positron emission tomography
MIDAS: metal ion–dependent adhesion site
MIM: Mendelian Inheritance in Man
MIP-1α: macrophage inflammatory protein 1α
miR: micro–ribonucleic acid
MIS: minimally invasive surgery
MKI: mitosis-karyorrhexis index
MLASA: mitochondrial myopathy with lactic acidosis and sideroblastic anemia

MLD: metachromatic leukodystrophy
MLL: mixed-lineage leukemia
mM: millimolar
MMA: methylmalonic acid
MMC: mitomycin C
MMF: mycophenolate mofetil
MMP: matrix metalloproteinase
MMP-25: membrane type matrix metalloproteinase 25; the membrane-associated metalloproteinase leukolysin
MoAb: monoclonal antibody
M6P: mannose 6-phosphate
MPD: myeloproliferative disease
MPCF: multiparameter flow cytometry
MPGM: monophosphoglycerate mutase
Mpl: ligand for the myeloproliferative ligand receptor
MPO: myeloperoxidase
MMR: major molecular response
MRP: multidrug resistance-associated protein
MPS: Montreal platelet syndrome, mucopolysaccharidosis
MPS I: mucopolysaccharidosis I
MPS I H: Hurler disease
MPS III: Sanfilippo disease
MPS III A: Sanfilippo disease III A
MPS III B: Sanfilippo disease III B
MPS VI: Maroteaux-Lamy disease
MPS VII: Sly syndrome
MPSV4: meningococcal polysaccharide vaccine
MPV: mean platelet volume
M_r: molecular weight
MRA: magnetic resonance angiography
MRI: magnetic resonance imaging
MRC: Medical Research Council
MRE11A: meiotic recombination 11 homolog A
mRNA: messenger RNA
mRNP: messenger ribonucleoprotein
MRP2: multidrug resistance–associated protein 2 (a.k.a. ABCC2, cMOAT)
MRT: malignant rhabdoid tumor
ms: millisecond
MSC: multipotent mesenchymal stem cells
MSCV: murine stem cell virus
MSH: Multicenter Study of Hydroxyurea
MSH6: MutS homologue 6
MSMD: mendelian susceptibility to mycobacterial diseases
MSP1: *Plasmodium falciparum* merozoite surface protein 1
MST: metanephric stromal tumor
MTD: maximum tolerated dose
mtDNA: mitochondrial DNA
mTEC: medullary thymic epithelial cell
MTHFD1: methylenetetrahydrofolate dehydrogenase (NADP+ dependent) 1
MTHFR: methylenetetrahydrofolate reductase (methylene-THF reductase)
mTOR: mammalian target of rapamycin
MTTP: microsomal triglyceride transfer protein
MTP1: metal tolerance protein 1
Munc: mammalian homolog of *Caenorhabditis elegans* unc
MVB: multivesicular body
MWC: Monod, Wyman, and Changeaux model
MYD88: myeloid differentiation primary response gene (88)
MYHIIA: myosin heavy chain IIA
MYO5A: myosin 5 Va

N

NAA: *N*-acetylaspartate
NACHRI: National Association of Children's Hospitals and Related Institutions
NAD: nicotinamide adenine dinucleotide
NAD 47/89: neutrophil actin dysfunction with 47- and 89-kD protein abnormalities
NADH: reduced nicotinamide adenine dinucleotide
NADP: nicotinamide adenine dinucleotide phosphate
NADPH: reduced nicotinamide adenine dinucleotide phosphate
NAFLD: nonalcoholic fatty liver disease
NAIT: neonatal alloimmune thrombocytopenia
NANT: the New Approaches to Neuroblastoma Therapy consortium
NAP: neutrophil-activating protein
NAP-2: neutrophil-activating protein 2
NAT: nucleic acid testing
NATP: neonatal alloimmune thrombocytopenic purpura
NB-DGJ: *N*-butyldeoxygalactonojirimycin
NBS: Nijmegen breakage syndrome
NBT: nitroblue tetrazolium
NCI: National Cancer Institute
NCV: nerve conduction velocity
NDPase: nucleoside diphosphatase
NE: neutrophil elastase
NEMO: NF-κB essential modulator
NET: neutrophil extracellular trap
NF-1: neurofibromatosis type 1
NF-AT: nuclear factor of activated T cells
NF-κB: nuclear factor κB
NGAL: neutrophil gelatinase–associated lipocalin
NGF: nerve growth factor
NH: neonatal hemochromatosis
NHANES: National Health and Nutrition Examination Survey
NHEJ: nonhomologous end joining
NHL: non-Hodgkin's lymphoma
NHLBI: National Heart, Lung, and Blood Institute
NICU: neonatal intensive care unit
NIH: National Institutes of Health
NIK: NF-κB–inducing kinase
NK: natural killer (cell)
NKT: natural killer T cell
NLR: NOD-like receptor
NLPHL: nodular lymphocyte–predominant Hodgkin lymphoma
nm: nanometer
NMDP: National Marrow Donor Program
NMR: nuclear magnetic resonance
NNJ: neonatal jaundice
NO: nitric oxide
NOD: nonobese diabetic

NOS: nitric oxide synthase
NOX: NAD(P)H oxidase
NPA: Niemann-Pick disease type A
NPB: Niemann-Pick disease type B
NPC: Niemann-Pick disease type C
NR: nephrogenic rest
Nramp2: natural resistance-associated macrophage protein 2
NRAS: neuroblastoma RAS viral (v-ras) oncogene homolog
Nrf-1: nuclear regulatory factor 1
NRTI: nucleoside reverse transcriptase inhibitors
ns: nanosecond
NS: Noonan syndrome
NSAID: nonsteroidal anti-inflammatory drug
NSE: nonspecific esterases
NSCLC: non–small cell lung cancer
NSHL: nodular sclerosis Hodgkin lymphoma
NTBI: non–transferrin-bound iron
NTD: neural tube defect
nTreg: natural Treg
NuMA: nuclear mitotic apparatus (protein)
NWTSG: National Wilms Tumor Study Group

O

O_2: oxygen
OATP: organic acid–transporting polypeptide
OCA: oral contraceptive agent
OCS: open canalicular system
OCT1: organic cation transporter-1
ODC1: ornithine decarboxylase–1
OF: osmotic fragility
OGT: orogastric tube
OHCbl: hydroxycobalamin
OLTX: orthotopic liver transplant
OMIM: Online Mendelian Inheritance in Man
OMS: opsoclonus-myoclonus syndrome
OPG: Optic pathway gliomas
OPSI: overwhelming postsplenectomy infection
OR: odds ratio
OS: Omenn syndrome; overall survival
OSA: osteosarcoma
OSM: oncostatin M
OSMR: oncostatin M receptor
oxy-Hb: oxygenated hemoglobin

P

PA: phosphatidic acid
PAF: platelet-activating factor
PAFc: polymerase-associated factor complex
PAGE: polyacrylamide gel electrophoresis
PAI-1: plasminogen activator inhibitor 1
PAIgG: platelet-associated IgG
PALS: periarterial (or periarteriolar) lymphoid sheath
PAMP: pathogen-associated molecular pattern
PANDAS: pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections
PAR: protease-activated receptor
PAS: periodic acid–Schiff
PBG: porphobilinogen
PBG-D: porphobilinogen deaminase
PBREM: phenobarbital-responsive enhancer module
PBSC: peripheral blood stem cell
PC: phosphatidylcholine
PCBP1: poly C–binding protein 1
PCC: prothrombin complex concentrate
PCFT: proton-coupled folate transporter
PCH: paroxysmal cold hemoglobinuria
PCP: *Pneumocystis carinii* pneumonia
PCR: polymerase chain reaction
PCT: porphyria cutanea tarda
PCV: polycythemia vera
PCV7: 7-valent pneumococcal polysaccharide vaccine
PCV23: 23-valent pneumococcal polysaccharide vaccine
PD-1: programmed death 1
PDB: Protein Data Bank
PDGF: platelet-derived growth factor
PDGFB: platelet-derived owth factor β
PE: phosphatidylethanolamine; pulmonary embolism
PEBP2: polyomavirus enhancer–binding protein 2
PECAM-1: platelet–endothelial cell adhesion molecule 1
PEG: polyethylene glycol
PEG-ADA: polyethylene glycol conjugated ADA
PEG-MGDF: pegylated megakaryocyte growth and development factor
PEMR: progressive epilepsy with mental retardation
PET: partial exchange transfusion
PF4: platelet factor 4
PFA-100: Platelet Functional Analyzer 100
PFK: phosphofructokinase
PFS: progression-free survival
PFT: pulmonary function test
PGC-1a: peroxisomal proliferator–activated cofactor 1α
PGD: preimplantation genetic diagnosis
6-PGD: 6-phosphogluconate dehydrogenase
PGI_2: prostaglandin I_2 (prostacyclin)
PGK: phosphoglycerate kinase
PH: Pleckstrin homology
PHA: phytohemagglutinin
PHS: polycythemia hyperviscosity syndrome
PHT: primary hypertension; pulmonary hypertension
P_i: inorganic phosphate
PI: phosphatidylinositol
PIDD: primary immunodeficiency disease
PIG-A: phosphatidylinositol glycan class A (gene: *PIGA*)
PI3: phosphoinositide 3′
PI3K: phosphatidylinositol 3′-kinase
PIK3R2: phosphoinositide-3-kinase, regulatory subunit 2 (beta)
PIP: phosphatidylinositol 4-phosphate
PIP_2: phosphatidylinositol 4,5-bisphosphate
PIP_3: phosphatidylinositol 3,4,5-triphosphate
PIT: plasma iron turnover
PIVKA: protein induced by vitamin K antagonists
PK: pyruvate kinase
PKA: protein kinase A
PKB: protein kinase B
PKC: protein kinase C
PKG: protein kinase G
PKR: protein kinase regulated by RNA

PLC: phospholipase C
PLCγ: phospholipase Cγ
PLCγ2: phospholipase Cγ2
PLDN: pallidin
PLK1: polo-like kinase–1
PLNR: perilobar nephrogenic rests
PLP: pyridoxal 5-phosphate
PLTP: phospholipid transfer protein
PM: primary myelofibrosis
PMA: phorbol myristate acetate
PMBCL: Primary mediastinal (thymic) large B-cell lymphoma
PMD: AU QUERIED
PML: progressive multifocal leukoencephalopathy
PMN: polymorphonuclear neutrophil
PMPS: Pearson marrow-pancreas syndrome
PMS2: postmeiotic segregation 2
PN: parenteral nutrition
P-5′-N: pyrimidine-5′-nucleotidase
PN2/APP: protease nexin-2/amyloid β-protein precursor
PNET: primary neuroectodermal tumor
PNH: paroxysmal nocturnal hemoglobinuria
POD: PML oncogenic domains
POG: Pediatric Oncology Group
PNP: purine nucleoside phosphorylase
PNPD: purine nucleoside phosphorylase deficiency
Po_2: partial pressure of oxygen
PPCA: protective protein cathepsin A
PPO: protoporphyrinogen oxidase
PPP: platelet-poor plasma
PPTID: pineal parenchymal tumor of intermediate differentiation
PPTP: Pediatric Preclinical Testing Program
PR: partial remission
pRBCs: packed red blood cells
PRC2: Polycomb repressive complex 2
PRCA: pure red cell aplasia
PRCC: papillary renal cell carcinoma
PRES: Posterior reversible leukoencephalopathy
PRETEXT: pretreatment imaging-defined staging protocol
PRF1: perforin
PRKDC: protein kinase, DNA-activated, catalytic polypeptide
PROWESS: Protein C Worldwide Evaluation in Severe Sepsis (trial)
PRP: platelet-rich plasma
PRPP: 5-phosphoribosylpyrophosphate
PRR: pattern recognition receptor
PS: Pearson's marrow-pancreas syndrome; phosphatidylserine
PSA: prostate-specific antigen
PSD95: postsynaptic density protein of 95 kD
PSGL-1: P-selectin glycoprotein ligand-1
p-SMAC: peripheral central supramolecular activation cluster
PT: prothrombin time
PTB: phosphotyrosine binding
PTD: partial tandem duplication
P-TEFB: positive transcription elongation factor b
PTH: parathyroid hormone
PTK: phosphotyrosine kinase
PTLD: posttransplant lymphoproliferative disease
PTP: posttransfusion purpura
PTS: postthrombotic syndrome
PTT: partial thromboplastin time
PUS1: pseudouridylate synthase 1
PV: polycythemia vera
PXA: Pleomorphic xanthroastrocytomas

Q

QoL: quality of life

R

RA: refractory anemia
RAB27A: member *RAS* oncogene family 27A
***RAD*:** recombinase-activating gene
RAEB: refractory anemia with an excess of blasts
RAEBIT (RAEB-T): RAEB in transformation
***RAG*:** recombination-activating gene
***RAG1* and *RAG2*:** recombinase activating gene 1 and 2
RANK: receptor activator of nuclear factor κB
RANTES: regulated on activation, normal T-cell expressed and secreted
RAR: retinoic acid receptor
RARS: refractory anemia with ringed sideroblasts
RBC: red blood cell
RCC: renal cell carcinoma
RCT: randomized control trial
RDA: recommended dietary allowance
REAL: Revised European-American Classification of Lymphoid Neoplasms
RECIST: Response Evaluation Criteria in Solid Tumors
REM: rapid eye movement
RES: reticuloendothelial system
RDS: respiratory distress syndrome
RDW: red cell distribution width, red cell volume distribution width
RFC: reduced folate carrier
RFLP: restriction fragment length polymorphism
rFVIIa: recombinant activated factor VII
RFX5: regulatory factor X, 5
RFXANK: regulatory factor X-associated ankyrin-containing protein
RFXAP: regulatory factor X-associated protein
RGD: arginine, glycine, aspartic acid
Rh: rhesus
RhAG: Rh-associated glycoprotein
rhG-CSF: recombinant human granulocyte colony-stimulating factor
RhoH: Ras homology family member H
r-HuEPO: rhEPO, rHuEPO, recombinant human erythropoietin
RIG: retinoic acid–inducible gene
RIAM: $Rap1_{GTP}$-interacting adaptor molecule
RIS: reduction of immunosuppression
RLR: RIG-1–like receptor
RMC: renal medullary carcinoma
RMRP: RNase mitochondrial RNA processing

RNA: ribonucleic acid
rNAPc2: recombinant nematode anticoagulant protein c2
RNP: ribonucleoprotein
ROHHAD: rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation
ROS: reactive oxygen species
RPA: replication protein A
RPE: retinal pigment epithelium
RPL: ribosomal protein of the large ribosomal subunit
RPS: ribosomal protein of the small ribosomal subunit
RPS19: ribosomal protein S19
RR: rate ratio; response rate
rRNA: ribosomal RNA
RS: Rotor syndrome
RSC: reversibly sickled cell
RSP-2: ring surface protein 2
RSV: respiratory syncytial virus
RT: reverse transcriptase
RTA: renal tubular acidosis
RTK: receptor tyrosine kinase; rhabdoid tumor of the kidney
rVIIa: recombinant factor VIIa
RVT: renal vein thrombosis
RVV: Russell viper venom

S

SAA: severe aplastic anemia
SABD: spectrin-actin binding domain
SADNI: specific antibody deficiency with normal immunoglobulins
SAHA: suberoylanilide hydroxamic acid
SAGE: serial analysis of gene expression
SAO: Southeast Asian ovalocytosis
SAP: SLAM-associated protein
SARS: severe acute respiratory syndrome
SBB: Sudan black B
SBDS: Shwachman-Bodian-Diamond syndrome
SCA: sickle cell anemia
Sca-1: stem cell antigen 1
SCI: silent cerebral infarct
SCID: severe combined immunodeficiency disease
SCD: sickle cell disease
SCDSC: subacute combined degeneration of the spinal cord
SCF: stem cell factor
SCFR: stem cell factor receptor
scFv: single-chain variable fragments
SCID: severe combined immunodeficiency
SCN: severe congenital neutropenia
SCNIR: Severe Chronic Neutropenia International Registry
SCT: sacrococcygeal teratomas; stem cell transplantation
SD: standard deviation
SDF-1: stromal cell–derived factor 1
SDS: Shwachman-Diamond syndrome; sodium dodecyl sulfate
SDS-PAGE: sodium dodecyl sulfate–polyacrylamide gel electrophoresis
SEER: Surveillance Epidemiology and End Results
SEGA: subendymal giant cell astrocytoma
SERCA: sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase
SF3B1: splicing factor 3B subunit 1
SGD: specific (secondary) granule deficiency
SH2: src homology domain 2
SHD: sex hormone–binding domain
SH2D1A: SH2-containing protein 1A, Src homology 2 domain–containing protein
Shh: Sonic hedgehog
SHIP1: SH2 domain–containing inositol 5′-phosphatase 1
sHLH: secondary hemophagocytic lymphohistiocytosis
SHML: sinus histiocytosis with massive lymphadenopathy
SHP-2: SH2 domain–containing protein tyrosine phosphatase-2
SIFD: sideroblastic anemia, immunodeficiency, fever, and developmental delay
SIGAD: selective IgA deficiency
sIgM: surface IgM
SIOP: International Society of Paediatric Oncology
SIR: standardized incidence ratio
SIV: simian immunodeficiency virus
S-JIA: systemic onset juvenile idiopathic arthritis
SLAM: signaling lymphocyte activation molecule
SLC4A: solute carrier family 4A
SLC11A2: solute carrier family 11, member 2
SLC19A2: solute carrier family 19 (thiamine transporter), member 2
SLC25A37: solute carrier family 25 (mitochondrial iron transporter), member 37
SLC40A1: solute carrier family 40 member 1
SLE: systemic lupus erythematosus
SL-IC: severe combined immunodeficiency (SC)-ID mouse leukemia–initiating cell
SLP3: stomatin-like protein 3
SLP76: SH2 domain–containing leukocyte protein of 76 kD
SM: sphingomyelin; systemic mastocytosis
SMAC: supramolecular activation cluster
SMARCAL1: SWI/SNF related, matrix associated, actin dependent regulator of chromatin, subfamily a-like 1
SMC3 and SMC1A: structural maintenance of chromosomes 3 and 1A
SMD: spondylometaphyseal dysplasia
SMMHC: smooth muscle myosin heavy chain
SMN: second malignant neoplasms
Smo: Smoothened receptor
SMRT: silencing mediator of retinoid and thyroid receptors
SNARE: soluble *N*-ethylmaleimide–sensitive attachment protein receptor
snoRNA: small nucleolar RNA
SNP: single nucleotide polymorphism
SOCbl: sulfitocobalamin
SOCS: suppressor of cytokine signaling
SOD2: superoxide dismutase 2
SOS: sinusoidal obstruction syndrome; son of sevenless (protein)
SOT: solid organ transplantation
S-PCT: sporadic porphyria cutanea tarda
SP: single-positive

SP110: SP110 nuclear body protein
SPD: storage pool deficiency
sPLA2: secretory phospholipase A_2
SQUID: superconducting quantum interference device
SRC: SCID-reconstituting cell
SREBP: sterol regulatory element-binding proteins
SRT: substrate reduction therapy
SSCP: single-strand conformation polymorphism
SSP: stage-selector protein
STAG: stromal antigen 2
STAT: signal transducer and activator of transcription
STEAP3: six-transmembrane epithelial antigen of prostate 3
sTfR: serum transferrin receptor
STIM1: stromal interacting molecule 1
STOP: Stroke Prevention Trial in Sickle Cell Anemia
STR-HSC: short-term–reconstituting hematopoietic stem cell
Stx: Shiga-like toxin
STX11: syntaxin 11
STXBP2: syntaxin binding protein 2
SUMF1: sulfatase-modifying factor
SVC: superior vena cava
SWI/SNF: switch/sucrose nonfermentable
SWiTCH: Stroke With Transfusions Changing to Hydroxyurea study

T

TACI: transmembrane activator and calcium modulator and cyclophilin ligand interactor
TACL: Therapeutic Advances in Childhood Leukemia and Lymphoma consortium
TAFI: thrombin-activatable fibrinolysis inhibitor
TALEN: transcription activator-like effector nucleases
T-ALL: T-cell acute lymphoblastic leukemia
T antigen: Thomsen-Friedenreich cryptoantigen
TAM: transient abnormal myelopoiesis
TAMs: tumor-associated macrophages
TAMV: time-averaged maximum velocity
TAP1 or TAP2: transporter associated with antigen processing 1 or 2
TAPS: Alternatives Preoperatively in SCD
TAPA1: target of antiproliferative antibody 1
TAR: thrombocytopenia–absent radius (syndrome)
TAT: thrombin-antithrombin complex
TBI: total-body irradiation
TBK1: TANK-binding kinase 1
TBP: TATA-binding protein
TBX1: T-box 1
TcB: transcutaneous bilirubin
TCD: transcranial Doppler
TCDD: 2,3,7,8-tetrachlorodibenzo-*p*-dioxin
TCN2: transcobalamin II
TCR: T-cell antigen receptor, T-cell receptor
TCT: thrombin clotting time
TD: thymus dependent (antigen)
TdT: terminal deoxyribonucleotidyl transferase
TE: thromboembolism
TEC: transient erythroblastopenia of childhood
TEG: thromboelastography
TEMRA: T effector memory cell CD45RA+
TERT: telomerase reverse transcriptase
TF: tissue factor
TFEB: transcription factor EB
TFH: follicular helper T cell
TFPI: tissue factor pathway inhibitor
TFR2: transferrin receptor 2
TGA: thrombin generation assay
TGN: thioguanine nucleotides
TGF-β: transforming growth factor β
TGTP: 6-thioguanosine 5-triphosphate
TH: tyrosine hydroxylase
tHcy: plasma total homocysteine
THF: 5,6,7,8-tetrahydrofolate
THI: transient hypogammaglobulinemia of infancy
TI: thymus independent (antigen)
TIA: transient ischemic attack
TIBC: total iron-binding capacity
TIC: tumor-initiating cell
TICAM1: TIR domain-containing adapter molecule 1
TIMP: tissue inhibitor of matrix metalloproteinase–2
TIPS: intrahepatic portosystemic shunting
TKI: tyrosine kinase inhibitor
TL: transient leukemia
TLR: Toll-like receptor
TLR2: Toll-like receptor 2
TLS: translesion synthesis
TLT-1: TREM cells–like transcript-1
TM: tropomyosin
TMC: transmembrane channel-like
TMD: transient myeloproliferative disorder
TM8: transmembrane domain 8
TMD: transient myeloproliferative disorder
TMod: tropomodulin
TMP-SMX: trimethoprim-sulfamethoxazole
TMPRSS6: transmembrane protease, serine 6
7-TMR: seven-transmembrane–spanning receptor
7-TMS: seven-transmembrane–spanning domain
TNF: tumor necrosis factor
TNF-α: tumor necrosis factor-α
TNFRSF: TNF receptor superfamily
TNFSF: TNF superfamily
TNM: tumor-nodes-metastasis
TOF: time-of-flight (imaging)
TORCH: toxoplasmosis, rubella, cytomegalovirus, and herpesvirus infections
tPA: tissue plasminogen activator
TPE: therapeutic plasma exchange
TPH: transplacental hemorrhage
TPI: triose phosphate isomerase
TPMT: thiopurine methyltransferase
TPN: total parenteral nutrition
TPO: thrombopoietin
TPOR: thrombopoietin receptor
TPR: tetratricopeptide repeat
TQM: total quality management
TRAF: TNF receptor–associated factor
TRAF3: TNF receptor-associated factor 3
TRAIL: tumor necrosis factor–related apoptosis-inducing ligand
TRALI: transfusion-related acute lung injury

TRAP: Trial to Reduce Alloimmunization to Platelets
TREC: T-cell receptor excision circle, T-cell receptor gene excision circle
Treg: T-regulatory
TREM, TREM-1, TREM-2: triggering receptor expressed on myeloid cells (1, 2, etc)
TfR: transferrin receptor
TRIF: Toll-interleukin-1 receptor domain-containing adapter protein inducing interferon β
TRJV: tricuspid regurgitant jet velocity
TRK: tropomyosin receptor kinase
TRM: treatment-related mortality
TRMA: thiamine-responsive megaloblastic anemia
tRNA: transfer RNA
TSB: total serum bilirubin
TSH: thyroid-stimulating hormone
TSLC: tumor suppressor in lung cancer–1
TSLP: thymic stromal thymopoietin
TT: thrombin time
TTP: thrombotic thrombocytopenic purpura
TTT: transpupillary thermotherapy
TTTS: twin-twin transfusion syndrome
TVTG: topotecan, vinorelbine, thiotepa, dexamethasone, and gemcitabine
TWSG1: twisted gastrulation 1
TXA_2: thromboxane A_2
TYK2: tyrosine kinase 2
TYMS: thymidylate synthetase

U

UBIL: unconjugated bilirubin
UCB: umbilical cord blood
UDP: uridine diphosphate
UDPG: uridine diphosphate glucose
UDPGA: uridine diphosphate glucuronic acid
UDPGT1: Uridine diphosphogluconosyl transferase 1
UDPNAG: uridine diphosphate *N*-acetylglucosamine
UGT1A1: UDP glucuronosyltransferase 1A1 gene
UKCCG: United Kingdom Children's Cancer Group
ULVWF: *unusually large multimers of VWF*
UMP: uridine monophosphate
UNC: unc homolog *(C. elegans)*
UNG: uracil nucleoside glycosylase
UNOS: United Network of Organ Sharing
uPA: urokinase plasminogen activator
uPAR: uPA receptor
UPR: unfolded protein response
URD: unrelated donor
URO-D: uroporphyrinogen decarboxylase
URO3-S: uroporphyrinogen III synthase
UTI: urinary tract infection
UTP: uridine triphosphate
UTR: untranslated regions
UV: ultraviolet

V

V: variable
VACTERL: vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, and/or esophageal atresia, renal agenesis and dysplasia, and limb defects
VAMP-1, -2: vesicle-associate membrane protein 1, 2, etc
VASP: vasodilator-stimulated phosphoprotein
VATER: vertebral defects, imperforate anus, tracheoesophageal fistula, renal defects and radial dysplasia
VCA: viral capsid antigen
VCAM-1: vascular cell adhesion molecule 1
Vd: volume of distribution
VDJ: variable, diversity, joining
VDRL: Venereal Disease Research Laboratory
VEGF: vascular endothelial growth factor
VHL: von Hippel-Lindau (protein)
VK: vitamin K
VK1: phylloquinone
VK2: menaquinone
VKDB: vitamin K–dependent bleeding
VKDP: vitamin K–dependent protein
VKOR: vitamin K 2,3-epoxide reductase
VLA-4: very late antigen 4
VLBW: very low birth weight
VLDL: very-low-density lipoproteins
VOD: veno-occlusive disease
VODI: veno-occlusive disease with immunodeficiency
VP: variegate porphyria
VP-16: etoposide
VTE: venous thromboembolism
V/Q: ventilation-perfusion
VWD: von Willebrand disease
VWF: von Willebrand factor
VWF:Ag: von Willebrand factor antigen
VWF:CB: collagen-binding assay for von Willebrand factor
VWFpp: von Willebrand factor propeptide
VWF:RCo: VWF activity by ristocetin cofactor assay
VZV: varicella-zoster virus

W

WAGR: **W**ilms tumor, **A**niridia, **G**enitourinary abnormalities, and **R**etardation
WAS: Wiskott-Aldrich syndrome
WASP: Wiskott-Aldrich syndrome protein
WBC: white blood cell
WBRT: whole-brain radiotherapy
WHIM: warts, hypogammaglobulinemia, infections, myelokathexis (syndrome)
WIP: WASP-interacting protein
WIPF1: WAS/WASL interacting protein family, member 1
WNDP: Wilson disease protein
WNV: West Nile virus
WRK: Woodward's reagent K
WSXWS: Trp-Ser-Xaa-Trp-Ser

X

X-CGD: X-linked chronic granulomatous disease
XHIM: X-linked immunodeficiency with normal or elevated IgM
XIAP: X-linked inhibitor of apoptosis

XLA: X-linked agammaglobulinemia
XLF: XRCC4-like factor
XLP1, XLP2: X-linked lymphoproliferative syndrome type 1 and 2
XLPD: X-linked lymphoproliferative disease
XLSA: X-linked sideroblastic anemia
XLSA/A: X-linked sideroblastic anemia with ataxia
XLT: X-linked thrombocytopenia
XPD: xeroderma pigmentosum disease
XRT: x-ray therapy; pulmonary radiation therapy
XSCID: X-linked severe combined immunodeficiency

Y

YARS2: tyrosyl-tRNA synthetase 2, mitochondrial
YTRF: tyrosine-threonine-arginine-phenylalanine (sequence)

Z

ZAP-70: TCRζ–associated protein of 70 kD
ZBTB24: zinc-finger and bric-a-brac, tramtrack, broad complex-domain-containing 24
ZIP: zinc transporter
ZFN: zinc-finger nucleases
ZPI: protein Z–dependent protease inhibitor
ZPP: zinc protoporphyrin

CONCLUSION

This chapter offers a review of the anatomy and physiology of normal hematopoiesis that is intended to provide a basis for understanding the marrow failure syndromes described at length in the following chapter. In this chapter we briefly discuss the phylogeny of hematopoiesis and describe marrow anatomy and the egress of recognizable hematopoietic cells from the marrow into the peripheral blood. A more detailed analysis then follows of the cellular bases of erythrocyte, granulocyte-macrophage, and megakaryocyte development, including discussions of the pluripotent stem cell and its niche, the more committed but still undifferentiated progenitor cells, and the differentiated precursors of the mature formed elements of the blood. Much of this chapter is devoted to the interactions of growth factors and the cells that produce them in the upregulation of hematopoiesis. The mechanisms of downregulation of hematopoiesis by cell interactions and cytokines are touched upon here, but they are less well understood despite the fact that they are likely to influence the pathophysiology of aplastic anemia and other marrow failure syndromes.

HISTORY*

That "blood is life" was appreciated by Empedocles in the fifth century BC. The theory that the vasculature contains blood, phlegm, black bile, and yellow bile, all revealed when freshly let blood is permitted to separate, is attributed to Polibus, the son-in-law of Hippocrates.

Servetus recognized the systemic and lesser circulations in the sixteenth century. He was burned at the stake, in part because he did not accept the dogma that blood must pass through the intraventricular cardiac septum. (Grant disapproval and, more recently, approval without funding have been substituted for immolation. The effects are not entirely dissimilar.)

In view of the present growth of knowledge of hematology, it is remarkable to realize that the concept of the circulation of the blood was finally established by Harvey in 1628, not even 400 years ago. This began the clinical application of blood transfusion, of which Pepys wrote "it gave rise to many pretty wishes as of the blood of a Quaker to be let into an Archbishop and such like."

In the mid–seventeenth century, Swammerdam observed red blood corpuscles in the microscope and Malpighi discovered the capillary circulation in the lung and in the omentum. But it was not until the nineteenth century that the source of blood cell production began to be successfully explored. Houston suggested that red cells were derived from leukocytes in the lymphoid system. Zimmerman believed that erythrocytes were derived from platelets, an opinion shared by Hayem. Addison, perhaps not surprisingly, attributed red cell production to the adrenals, and Reikert finally suggested that red cells might be produced in the embryonic liver. In fact, it was not until 1868 that Neumann demonstrated that red cells arise from precursors in the marrow. The modern understanding of the physiology of hematopoiesis then began.

PHYLOGENY

Much can be learned about the physiology of hematopoiesis from study of the evolution of oxygen transport, a subject reviewed by Lehman and Huntsman.[1]

One of the major advantages of mammalian life over that of invertebrates is the capacity to package large amounts of hemoglobin within cells. This permits the delivery of oxygen to tissues without the enormous increase in oncotic pressure that would be induced by a similar concentration of high–molecular-weight hemoglobin free in the plasma. The renewal rate of red cells is a function of metabolic rate or basal heat production. This is illustrated dramatically in studies of the animal kingdom, ranging from the turtle to the pygmy shrew, and by comparisons of red cell renewal in marmots during periods at ambient and cold temperatures,[2] in rats,[3] and in frogs.[4]

The production of blood cells in bone marrow is a late development in phylogeny. Red cells are found in the coelomic cavity of the worm, and are produced in the kidneys of the goldfish. The influence of oxygen demand on the production of red cells[5] is illustrated by the effects of hyperoxia on bled rats[6] and the behavior of the European eel, one of the few vertebrate forms that ordinarily lacks erythrocytes in its juvenile state. When the adult eel struggles against the current up the rivers of Europe, nucleated cells containing hemoglobin appear in its plasma. This influence of oxygen demand on respiratory pigment production is also illustrated in organisms that do not produce red cells, such as *Daphnia*, the English water flea, a creature that produces high–molecular-weight hemoglobin in its ovaries when it is exposed to low oxygen tension in stagnant ponds. The discovery of transcription factors that function as oxygen sensors provides a potential molecular explanation for these regulatory mechanisms.[7-10]

MARROW ANATOMY

The active red marrow space of a child is much greater than that of an adult, presumably because the high requirements for red cell production during neonatal life demand the resources of the entire production potential of the marrow. During postnatal life the demands for red cell production ebb, and much of the marrow space is slowly and progressively filled with fat (Fig. 1-1). In certain disease states that are usually associated with anemia, such as myeloid metaplasia, hematopoiesis may return to its former sites in the liver, spleen, and lymph nodes and may also be found in the adrenals, cartilage, adipose tissue, thoracic paravertebral gutters, and even in the kidneys.

The microenvironment of the marrow cavity is a vast network of vascular channels or sinusoids in which float fronds of hematopoietic cells. This complex area of cell biology and anatomy has been the subject of several reviews.[11-15] The vascular and hematopoietic compartments are joined by reticular fibroblastoid cells that form the adventitial surfaces of the vascular sinuses and extend cytoplasmic processes to create a lattice on which blood cells are found. The lattice itself is illustrated by reticulin stains of marrow sections (Fig. 1-2). The conformation of the meshwork of reticulin and the location of hematopoietic cells in the network of vascular sinuses are best illustrated by scanning electron microscopy (Fig. 1-3). The fibroblastoid network has two major functions: (1) it provides an adhesive framework onto which the developing cells are bound, and (2) it participates in the production by these cells of essential hematopoietic colony-stimulating factors,[16] to be discussed below. Cell-cell adhesion may be mediated by binding of the hematopoietic very late antigen 4 (VLA-4) integrin to stromal fibronectin or vascular cell adhesion molecule 1 (VCAM-1).[17-20] In addition, cytokine receptors such as KIT can bind to the membrane-bound form of stem cell factor (SCF),[21] and the extracellular matrix proteins secreted by

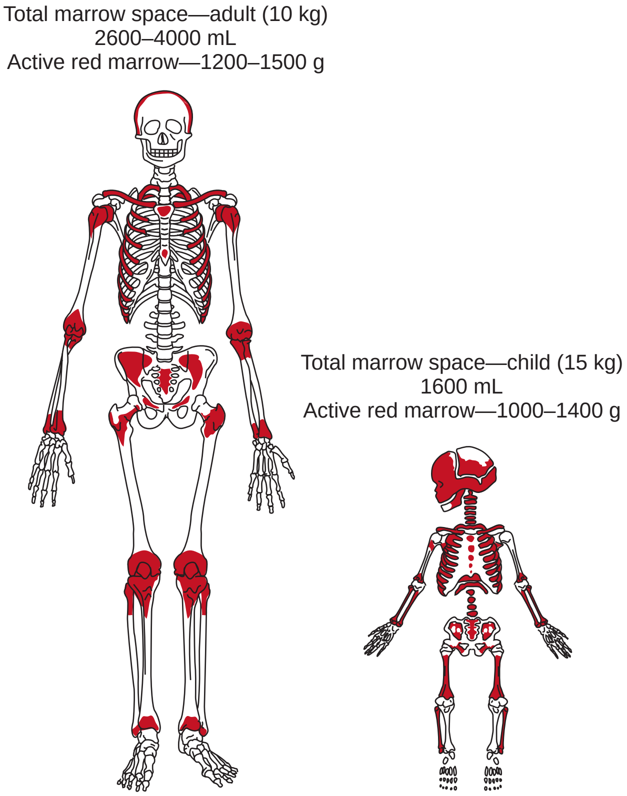
For more details, see also *Blood pure and simple* by the late Maxwell M. Wintrobe, New York, 1980, McGraw-Hill.



Total marrow space—adult (10 kg)
2600–4000 mL
Active red marrow—1200–1500 g
Total marrow space—child (15 kg)
1600 mL
Active red marrow—1000–1400 g

Figure 1-1 The comparison of active red marrow–bearing areas in the child and the adult. Note the almost identical amount of active red marrow in the child and adult despite a fivefold discrepancy in body weight. *(From MacFarlane RC, Robb-Smith AHT, editors:* Functions of the blood, *Oxford, 1961, Blackwell Scientific, p. 357.)*

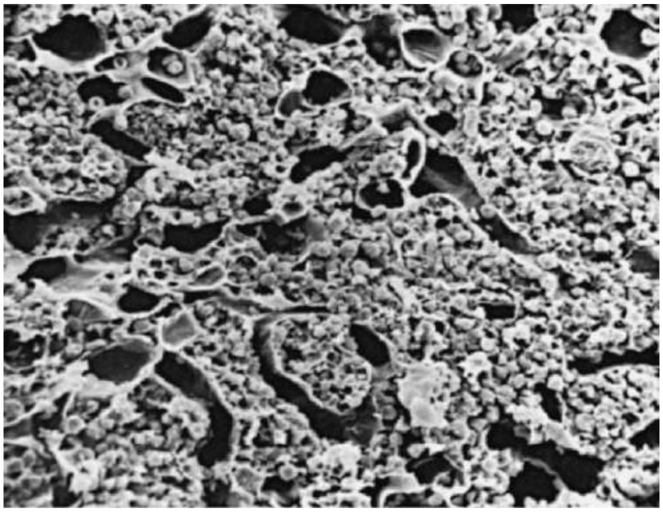


Figure 1-3 Scanning electron micrograph of rat femoral marrow. The hematopoietic cells are grouped between the interlacing network of vascular sinuses. Many cells are dislodged when the marrow is transected, and separate spaces are present where cells had been. *(From Lichtman MA, Chamberlain JK, Santillo PA: Factors thought to contribute to the regulation of egress of cells from marrow. In Gordon AS, Silber K, LoBue L, editors:* The year in hematology, 1978, *New York, 1978, Plenum Medical, p. 243–279.)*

stromal cells may actually provide a binding site for some growth factors or for hematopoietic cells.[22-24] In addition, chemokines, a family of small molecules, play major roles in stromal function. Specifically, stromal-derived factor 1 (SDF-1) is a potent attractant for hematopoietic cells (both mature leukocytes and progenitor cells that express its CXC chemokine receptor 4 [CXCR4]).[25] Gene disruption studies in mice show that both ligand and receptor are lethal in the embryonic stage, with defects in B lymphopoiesis and myelopoiesis.[26,27] These relate to a critical role for CXCR4 in bone marrow engraftment in immunodeficient nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice[28]; SDF-1 has been shown to activate the integrins VLA-4, VLA-5, and lymphocyte function–associated antigen 1 (LFA-1) on CD34+ cells.[29] Last, SDF-1 plays a role in the egress of progenitor cells from bone marrow to blood during stem cell mobilization.[30,31] Indeed, pharmacologic inhibition of the SDF-1 receptor CXCR4 with the drug plerixafor is employed clinically to enhance mobilization.[32]

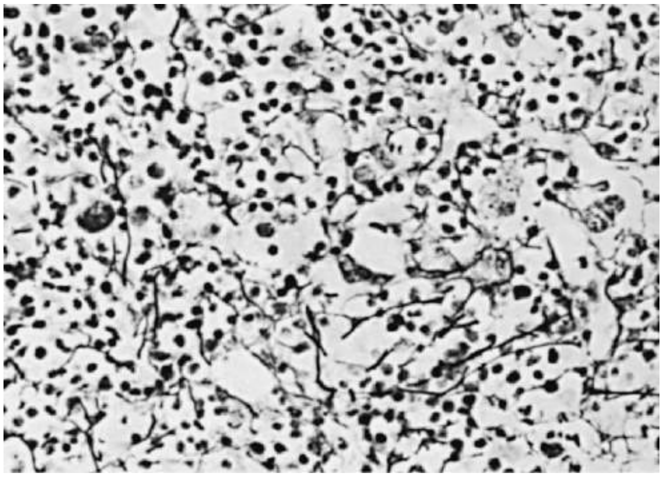

Figure 1-2 Bone marrow biopsy of a patient with mild myelofibrosis showing a slight increase in the number of reticulin fibers in a delicate discontinuous fiber network. (Gomori stain ×350.) *(From Lennert K, Nagai K, Schwarze EW: Patho-anatomical features of the bone marrow.* Clin Hematol *4:335, 1975.)*

A schema of the marrow circulation is shown in Figure 1-4. The central and radial arteries ramify in the cortical capillaries, which in turn join the marrow sinusoids and drain into the central sinus. Cells that egress from the marrow sinusoids then join the venous circulation through comitant veins. The inner, or luminal, surface of the vascular sinusoids is lined with endothelial cells, the cytoplasmic extensions of which overlap, or interdigitate, with one another. The escape of developing hematopoietic cells into the sinus for transport to the general circulation occurs through gaps that develop in this endothelial lining and even through endothelial cell cytoplasmic pores.

The location of the different hematopoietic cells is not random. Clumps of megakaryocytes are found adjacent to marrow sinuses. They shed platelets, the fragments of their cytoplasm, directly into the lumen. This reduces the requirement for movement of bulky mature megakaryocytes, a mobility characteristic of the granuloid- and erythroid-differentiated precursors as they approach the

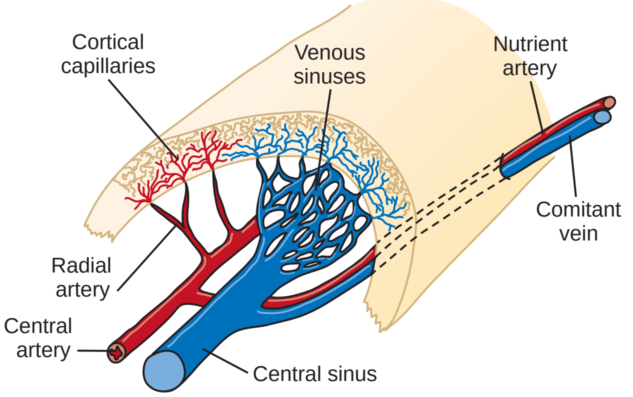

Figure 1-4 A schematic representation of the circulation of the marrow. The nutrient artery, central arteries, and radial arteries feed the cortical capillaries. The cortical capillaries anastomose with the marrow sinuses, which drain into the large central sinus. The central sinus enters the comitant vein by which the marrow effluent enters the systemic venous circulation. An interesting feature of the circulation of marrow is the transit of nearly all arterial blood through cortical capillaries before it enters the marrow sinuses. Not shown are the arterial communications from muscular arteries that feed the periosteum and penetrate the cortex to anastomose with intracortical vessels. *(From Lichtman MA, Chamberlain JK, et al: Factors thought to contribute to the regulation of egress of cells from marrow. In Silber K, LoBue J, et al, editors:* The year in hematology, 1978. *New York, 1978, Plenum Medical, p. 243–279.)*

point at which they egress from the marrow. A schema that illustrates the transfer of hematopoietic cells into the sinus is shown in Figure 1-5. Disruption of the function of microenvironmental cells inhibits long-term murine marrow cultures.[33] Such disruptions may be responsible for certain cases of aplastic anemia. In recent years significant attention has been paid to the cellular components of the hematopoietic stem cell (HSC) niche, with several reports of the role of osteoblasts as supportive microenvironmental cells that liberate critical cytokines such as SDF-1.[34-36] However, alternative views argue for a major role of vascular endothelium of the marrow sinusoids in sustaining HSCs (see Fig. 1-5).[37,38] See the review by Krause and Scadden[39] for further details.

HEMATOPOIETIC CELLS

Stem Cells

The concept that sustained hematopoiesis derives from pluripotent stem cells was first suggested in 1949 by Jacobson,[40] who showed that mice can be protected from the lethal affects of whole-body irradiation by exteriorization and shielding of the spleen. This protective effect was shown to be cell mediated by the observation that the injection of spleen cells could initiate recovery and reestablish hematopoiesis in irradiated animals.[41] The clonal nature of hematopoiesis and the concept that a single pluripotent stem cell exhibits the capacity to repopulate the entire hematopoietic system was first demonstrated experimentally by Till and McCulloch,[42] who also used the mouse as an experimental system. They found colonies of hematopoietic cells containing erythrocytes, granulocytes, macrophages, and megakaryocytes in the spleens of irradiated recipients within 10 days after transplant. Subsequent experiments using karyotypically marked donor cells confirmed the clonal origin of the differentiated cells in the colony, proving that a single multipotent stem cell had given rise to these differentiated cells.[43] It was also shown that each colony contained a number of stem cells that could again form a colony of differentiated progeny in a second irradiated recipient, demonstrating their self-renewal capacity. This is true only of spleen colonies that are present on days 12 to 14 (colony-forming unit–spleen,[CFU-S_{12}]). Colonies observed on days 7 to 8 after marrow infusion are transient, disappear by day 12, and are neither multipotential nor self-maintaining.[44] Under steady-state conditions no more than 10% of the CFU-S become committed to differentiation during any given 3-hour period. The demonstration of a stem cell that can differentiate to form progenitor cells for erythropoiesis, granulopoiesis, and megakaryopoiesis is consistent with subsequent observations in disease states such as chronic myelogenous leukemia[45,46] and polycythemia vera,[47,48] in which a clonal origin of abnormal erythroid, granulocytic, and megakaryocytic precursor cells and lymphocytes can be demonstrated.

The demonstration of a multipotent stem cell in adult bone marrow led to a systematic search for the ontogenic origins of HSCs. Experiments performed by Moore and Metcalf[49] demonstrated the presence of cells capable of repopulating the adult marrow in the yolk sac and the murine fetal liver.[42] Subsequent work has corroborated these observations.[50] It is widely accepted that the first blood cells that circulate in the mammalian embryo arise from the yolk sac. This so-called "primitive" blood lineage consists primarily of nucleated erythrocytes that express embryonic forms of hemoglobin.[51] The classic view of the developmental origins of HSCs holds that the first progenitors of the yolk sac later populate the fetal liver,[52,53] where they mature to become the "definitive" HSCs of the adult bone marrow, whose erythroid progeny express mature adult forms of beta hemoglobin. However, painstaking dissections of midgestation mouse embryos prior to the onset of blood circulation suggest that the HSCs that can engraft the bone marrow of an irradiated adult mouse first arise within the embryonic trunk.[54,55-57] Refinements of the anatomic location of these nascent definitive HSCs show their emergence from a specialized hemogenic endothelium along the base of the developing aorta,[58-62] where the first pulsations of the heartbeat serve as a trigger[63,64] to activate an endothelial-to-hematopoietic transition.[65,66] Debate persists, and some argue that HSCs may arise simultaneously in the yolk sac and intraembryonically from the hemogenic endothelium of the aorta.[67] Complicating the true origins of the first definitive HSCs further, the placenta also appears to be a source of HSCs during development,[68,69] although it remains possible that the stem cells arrive through the circulation from intraembryonic sources such as the hemogenic endothelium of the aorta. Alternatively, given its rich network of arteries, the placenta may indeed be a de novo producer of blood stem cells. The placenta is quantitatively a large source of HSCs during development.

Figure 1-5 A schematic diagram of the factors that may be involved in controlling stem cell regulation in the perivascular and endosteal niches as well as the release of marrow cells. The central relationship between the hematopoietic compartment and the marrow sinus is depicted. The stem cell niche is involved in the regulation of hematopoietic stem cell quiescence, self-renewal, mobilization, and differentiation; niches involve cell contact and secretory functions of osteolineage cells, osteoclasts, sinusoidal endothelial cells, macrophages, and mesenchymal stromal and stem cells *(MSCs)*, including CXCL12 abundant reticular cells *(CARs)*, sympathetic neurons, and extracellular matrix. There are nestin-positive stromal cells that are thought to be derived from neural crest, which support hematopoiesis. The drawing highlights the similarity of the egress process for the three major hematopoietic cells: reticulocytes in the top pathway, granulocytes and monocytes in the center pathway, and platelets in the lower pathway. Immature cells undergo biophysical changes under the influence of cytopoietins that favor egress. In the case of the reticulocyte, enucleation precedes egress. This is shown by the solid red inclusion in the perisinal macrophage representing nucleophagocytosis antecedent to digestion of the erythroblast nucleus. The cytoplasmic protrusion of the megakaryocyte presumably detaches itself from the cell and will further fragment into platelets in the circulation. *OPN,* Osteopontin. *(Modified from Lichtman MA, Chamberlain JK, et al: Factors thought to contribute to the regulation of egress of cell from marrow. In Silber K, LoBue J, et al, editors:* The year in hematology, 1978. *New York, 1978, Plenum Medical, p. 243–279.)*

The most primitive cells with the greatest self-renewal capacity reconstitute long-term hematopoiesis after transfer into irradiated recipient mice. These cells, termed long-term reconstituting hematopoietic stem cells (LTR-HSCs), were shown to be separable from CFU-S$_{12}$ in a limiting-dilution assay designed to detect and enumerate "cobblestone areas."[70] This assay is derived from the original "Dexter" technique for long-term culture of murine marrow in which CFU-S, colony-forming unit–granulocyte-macrophage (CFU-GM), and burst-forming unit–erythroid (BFU-E) flourish for many months on and within an adherent stromal monolayer.[71] The areas of active hematopoiesis have a "cobblestone" appearance. In the limiting-dilution assay, different concentrations of bone marrow cells are plated onto a series of microwells that contain a preestablished stromal monolayer, and at 5 weeks the cobblestone areas that comprise proliferating blast cells within the stromal cell layer are counted.[70] In cell separation experiments, their numbers correlate with a cell fraction that is characterized by low mitochondrial mass per cell (minimal retention of the supravital fluorochrome rhodamine-123); this Rho– cell fraction is enriched for marrow repopulating cells but depleted of CFU-S$_{12}$.[70,72] Intermediate and rapidly sedimenting cells contained more than 99% CFU-S$_{12}$ as well as the cells responsible for short-term reconstitution. In contrast, long-term reconstituting cells (>60 days) came from a slowly sedimenting fraction that contained only 0.25% CFU-S$_{12}$.

The stem cell model of hemopoiesis has parallels in other organ systems. That rapidly self-renewing epithelial tissues such as skin and intestine have stem cells that continually replenish the cells lost by differentiation is well described. However, the demonstration of the existence of neural stem cells[73,74] has raised the possibility that many organ systems might retain a population of self-renewing stem cells. Muscle satellite cells also appear to fulfill this role. These organ- or tissue-specific stem cells arise during early fetal development from embryonic stem cells of the inner cell mass of the blastocyst that are pluripotent and give rise to all cell types in the body.

Many assays have been proposed as "surrogate" stem cell assays, but until homogeneous populations can be evaluated in both in vitro and in vivo assays it will be impossible to determine the precise cell type measured by these methods. Fauser and Messner and others[46,75-77] demonstrated colonies in semisolid media that contain granulocytes, erythrocytes, monocytes, and megakaryocytes (CFU-GEMM) in methylcellulose cultures of human bone marrow. A unique type of in vitro blast cell colony that comprises small numbers of blast cells with higher self-renewal capacity (secondary colonies on replating) than CFU-GEMM has been described.[78] Evidence for the presence of pluripotent HSCs is also derived from the human "Dexter" technique for liquid culture of marrow, in which myeloid progenitors (mostly CFUs-GM) are sustained for about 2 months on and within an adherent stromal monolayer.[79,80] The progenitors can be detected by replating into methylcellulose with several growth factors at 5 to 8 weeks, thereby demonstrating that unipotent and multipotent cells are generated in this culture system. Eaves and colleagues[81] have adapted this long-term culture technique to a limiting=dilution assay in which long-term culture-initiating cells (LTC-ICs) can be quantitated after culture at different concentrations on a stromal layer for 5 weeks, followed by replating in methylcellulose to score for the number of wells that do not contain colonies. The analogous cobblestone area–forming cell (CAFC) assay has also been adapted to human cells.[82] The high proliferative potential colony-forming cell (HPP-CFC) assay that gives rise to macroscopically visible (>5 mm) in vitro colonies[83,84] is another method that measures the enormous proliferative capacity of primitive progenitor cells. In an effort to establish a more direct measure of the ability of human stem cells to reconstitute hematopoiesis, Dick and colleagues[85] developed an in vivo assay. In this method human cells are injected into immunodeficient nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice, and 5 to 8 weeks later the animals are sacrificed and tested for the presence of human cells in blood and progenitors in bone marrow. By limiting-dilution assay these SCID reconstituting cells (SRCs) can be quantitated. Because NOD/SCID mice develop thymic lymphomas that prevent long-term studies and have natural killer (NK) cell activity that confers graft resistance, improvements in the model have been achieved by using mice with additional truncated (NOG) or deleted (NSG) interleukin 2 receptor (IL-2R) common gamma chains[86,87]; these animals support a -fivefold higher level of CD34+ engraftment. Cell fractionation and gene marking studies provide some evidence that SRCs are more primitive than LTC-ICs.[88,89] Although SRCs may still be a heterogeneous population of cells that includes long-term repopulating HSCs, this assay provides a better measure of stem cell properties than the LTC-IC assay, especially with regard to the multipotent (i.e., myeloid and lymphoid) and self-renewal properties of HSCs. A tentative relationship of the cells measured in these different assays to the stem cell is shown in Figure 1-6.

Application of these assays and analysis of HSCs, in general, has been hindered by the low frequency of the cell in the hematopoietic population and the lack of reagents to identify stem cells. However, it is now possible to purify murine stem cells by several methods. Murine HSCs can be highly purified by density gradient centrifugation combined with labeling with antibodies, lectins, or

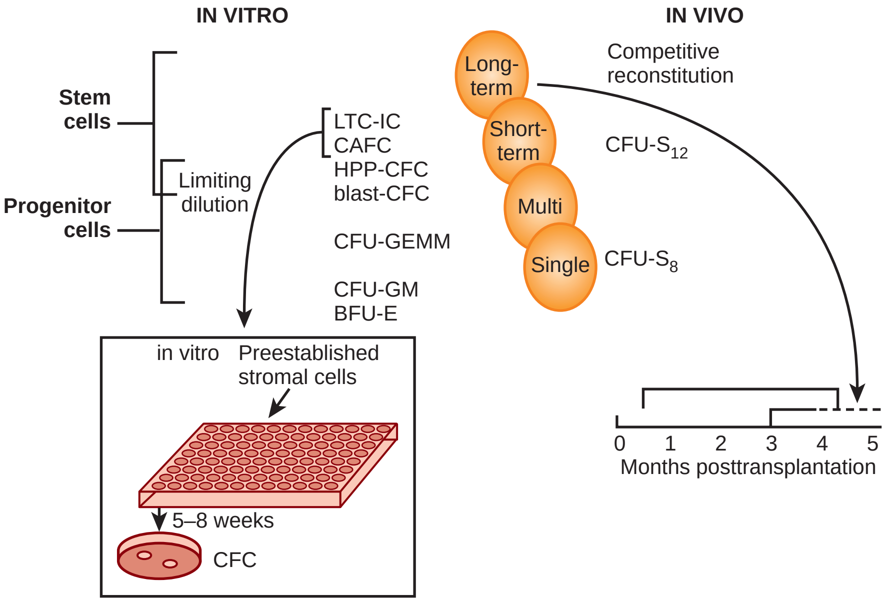

Figure 1-6 Schematic view of some general properties and assays for the heterogeneous cells that comprise the stem cell and progenitor cell compartments. As indicated on the diagram, cells capable of permanently reconstituting in vivo hematopoiesis are separable from cells that give rise to day 12 CFU-S, but the precise developmental stage of in vitro long-term culture initiating cells *(LTC-ICs)*, cobblestone area–forming cells *(CAFCs)*, high proliferative potential colony-forming cells *(HPP-CFCs)*, and blast CFCs is not established. In the progenitor compartment, mixed colonies of almost all lineage combinations have been described.

intracellular dyes (alone or in combination) followed by separation using fluorescence-activated cell-sorting (FACS), immunopanning, or immunomagnetic beads. Immunologic reagents that define murine stem cell populations include antibodies to Thy-1 (CD90), Kit, and stem cell antigen (Sca-1). Weissman and coworkers[90] used the FACS in combination with negative expression of T-cell, B-cell, granulocyte, and monocyte lineage-specific markers; low expression of Thy-1; and expression of Sca-1 to isolate HSCs. Transplantation of single Kit$^+$, Thy-1^{lo}, Lin–, Sca-1$^+$ (KTLS) cells can ensure long-term survival of lethally irradiated syngeneic recipients,[91] and approximately 20% of such cells are LTR-HSCs. Murine HSCs can be even further enriched using cell surface receptors of the signaling lymphocyte activation molecule (SLAM) family. HSCs are CD150+, CD244–, and CD48–, whereas multipotent progenitors lose CD150 expression and begin to express the other family members CD244 and CD48. Purification of CD150+, CD48–, and CD41– cells (CD41 is also expressed on megakaryocyte lineage cells) provides a population of cells 45% of which are LTR-HSCs.[92]

Expression of the CD34 antigen has been used to enrich for human stem cells. Although most colony-forming cells (CFCs) express both the CD34 and CD33 antigens, cells that give rise to CFC in long-term bone marrow cultures (i.e., pre-CFCs) can be separated by their expression of CD34, lack of expression of CD33, and intermediate forward light-scattering properties.[93] A G_0 CD34+ cell population has been isolated by exploiting the resistance of these cells to 5-fluorouracil (5-FU) in the presence of stem cell factor (SCF) and interleukin-3 (IL-3).[94] The G_0 cells are also positive for KIT, interleukin-6 receptor (IL-6R), and IL-1R, and they do not form progenitor-derived colonies upon direct culture in methylcellulose; after 5 weeks in culture on stromal cells, however, they do form primary colonies in methylcellulose 40% of which are replatable. The importance of CD34-positive marrow cells is emphasized by in vivo simian studies. Similar to human bone marrow, the CD34 antigen is expressed by a minority of baboon cells, and infusion of these cells isolated by immunoabsorption chromatography and FACS can reconstitute lymphohematopoiesis in lethally irradiated baboons.[95] The cloning of the murine CD34 complementary DNA (cDNA) has cast some doubt on expression of CD34 by LTR-HSCs, at least in the mouse. A monoclonal antibody raised to murine CD34–glutathione-S-transferase (GST) fusion protein was used to separate purified Sca-1+, Kit+, lin– bone marrow cells into CD34^{lo}/–, CD34^{lo}, and CD34+ fractions. Interestingly, long-term multilineage reconstitution was observed after transplantation of the CD34^{lo}/– cells, whereas the CD34+ fraction gave early but unsustained multilineage reconstitution.[91] These data are supported by experiments demonstrating that a tiny subset of murine bone marrow cells that exclude the Hoechst 33342 dye (called the *side population*) contains all the LTR-HSC activity but is CD34–.[96] It is possible that murine and primate LTR-HSCs differ in their expression of CD34; however, the human and primate transplants have not used very highly purified cells, and so it is also possible that CD34^{lo}/– cells could account for the long-term engraftment. Primate and human studies have also raised the possibility that HSCs do not express CD34.[97] When primitive human lin– cells are separated into CD34+ and CD34– fractions, the capacity to reconstitute hemopoiesis in immunodeficient mice (SRC) is found in both cell fractions.[98] A resolution to this controversy may come from the demonstration that resting murine HSCs are CD34–, whereas HSCs activated with 5-FU or cytokines such as G-CSF express the CD34 antigen.[99,100] Most interestingly, transplantation of activated CD34+ HSCs showed that these HSCs can lose CD34 expression after return of the recipients to the resting steady state and still retain the capacity to reconstitute secondary recipients, demonstrating that CD34 expression is reversible.[100] The current state of the art for HSC purification in the mouse includes the following marker profile: CD34–, CD150+, CD48–, CD41–, flt3–, and CD49b lo[101,102]; whereas in the human system, the current purification would exploit a different marker profile: CD34+, CD38–, CD45RA–, CD90+, and CD49f+, with further enrichment (capacity for single-cell engraftment) in a Rho$^-$ fraction of these cells.[103,104]

Progenitor Cells

The long-term repopulating HSCs of the marrow (LTR-HSCs) slowly self-replicate while occasionally (and stochastically) differentiating into cells that are multipotent but have reduced self-renewal capacity (called *myeloid lymphoid progenitors* in humans) and then into either common lymphoid progenitors or common myeloid progenitors. These cells can be prospectively isolated according to their expression of unique combinations of cell surface markers (Fig. 1-7).[105-108] Lymphoid differentiation will not be further considered here. The common myeloid progenitor differentiates into all of the progenitors of the blood cells other than lymphoid cells. These include more committed progenitors of the granulocyte, monocyte (GMPs), and eosinophil lineages or progenitors of the megakaryocyte, erythroid, and basophil lineages (MEPs). These cells can be isolated prospectively, and transplantation into lethally irradiated mice can confer transient but not long-term hematopoiesis.[109]

The current view of the mouse hierarchy derived from transplant studies has defined a linear track from LTR-HSCs to short-term reconstituting hematopoietic stem cells (STR-HSCs) (the latter most likely equivalent to the human myeloid lymphoid progenitor), and finally a multipotential progenitor, and then several branch points. There is a lymphocyte-myeloid multipotent progenitor (LMPP) that gives rise to common lymphoid progenitors and GMPs, whereas GMPs can also arise from common myeloid progenitors. There is certainly heterogeneity in these populations, and future fate mapping and sorting techniques may further define the populations.[108,110]

Erythroid Colony-Forming Cells

The erythroid progenitor compartment is invisible under the light microscope. Erythroid progenitors are committed progenitors of a single lineage derived from the stochastic differentiation of bipotential or multipotential

Figure 1-7 Major cytokine sources and actions and transcription factor requirements for hematopoietic cells. Cells of the bone marrow microenvironment, such as macrophages, endothelial cells, and reticular fibroblastoid cells, produce M-CSF, GM-CSF, G-CSF, IL-6, and, probably, SCF (cellular sources not precisely determined) after induction with endotoxin (macrophage) or IL-1/TNF (endothelial cells and fibroblasts). T cells produce IL-3, GM-CSF, and IL-5 in response to antigenic and IL-1 stimulation. These cytokines have overlapping actions during hematopoietic differentiation, as indicated, and for all lineages optimal development requires a combination of early-acting and late-acting factors. Transcription factors important for survival or self-renewal of stem cells are shown in *red* at the top, whereas stages of hematopoiesis blocked after the depletion of indicated transcription factors are shown in *red* for multipotent and committed progenitors.

progenitors[111] that are, in turn, derived from a tiny population of multipotential stem cells (see Fig. 1-7). In humans, the most primitive single-lineage committed erythroid progenitor is the erythroid burst-forming unit (BFU-E). In response to the combination of erythropoietin and either SCF, IL-3, or GM-CSF in vitro in semisolid (methylcellulose) cultures, BFU-E divide several times while still motile, thereby forming subpopulations of erythroid colony-forming units (CFU-E).[112] Then, each of the latter forms a large colony of proerythroblasts that go on to form more mature erythroblasts and even reticulocytes. The burstlike morphology of the colony is responsible for the name of the progenitor. The entire process requires about 2 weeks in vitro. Bone marrow also contains the more mature CFU-E that, under the influence of erythropoietin, form small colonies of erythroblasts in 7 days.

The murine erythroid progenitor phenotype (pre–CFU-E) can be defined as Sca-1–, Kit+, CD41–, CD150+, and endoglin+.[113] The human BFU-E counterpart is CD34+, CD38+, IL-3Rα–, and CD45RA–.

Granulocyte and Macrophage Colony-Forming Cells

The first colony assays relevant to the study of the production of granulocytes and monocytes in the mouse were described in 1965 by Pluznik and Sachs[115] and in 1966 by Bradley and Metcalf.[116] Analogous assays have been developed in the human system.[117] These groups demonstrated that individual cells derived from mouse spleen or bone marrow could give rise to colonies of up to several thousand differentiated granulocytes and/or macrophages in a soft agar medium. A period of 7 to 8 days was required for full maturation of these colonies (12 to 14 days is required in humans). Appropriate studies were performed to demonstrate the single-cell origin of the colonies. These studies also demonstrated that a single progenitor cell, which was termed the colony-forming unit in culture, or CFU-C, was capable of differentiation into both granulocytes and macrophages, giving rise to the designation CFU-GM. Unit gravity sedimentation and other separation methods have been used to demonstrate that CFU-GM represent a cell population distinguishable from the pluripotent stem cell.[118] Long-term liquid bone marrow cultures have been particularly helpful in defining humoral and cell-cell interactions that induce myeloid differentiation.[119] CFU-GM give rise to the more mature granulocyte and macrophage colony-forming units, CFU-G and CFU-M, respectively.[116,117] In addition, CFU-GM can be distinguished from the eosinophil progenitor, CFU-Eo, each arising independently from the common myeloid progenitor (CMP). Human CFU-GM are CD34+, CD38+, IL-3Rα^{lo}, and CD45RA–.[114]

Megakaryocyte Colony-Forming Cells

Figure 1-7 provides an accepted if idealized schema of lineage-restricted megakaryocyte progenitor development. Evidence strongly suggests that the initial phase of differentiation into erythrocyte and megakaryocyte commitment involves a single progenitor capable of giving rise to colonies of differentiated cells, all of which express a nuclear transcription factor known as GATA1.[120,121] Of great interest is the fact that another transcription factor, nuclear factor, erythroid 2 (NF-E2), has been shown to regulate platelet production.[122] Mice rendered NF-E2 deficient have increased numbers of immature megakaryocytes in the marrow but die from bleeding resulting from absence of platelets. The thrombocytopenia is due to a block late in megakaryocyte maturation. Interestingly, these animals do not show an increase in thrombopoietin levels, suggesting that the megakaryocyte mass rather than the platelet count regulates thrombopoietin production.

Precursors and Mature Cells

The erythroid precursor or erythroblast pool represents about one third of the marrow cell population in the normal child above the age of 3 years or in the adult. Proerythroblasts are the earliest recognizable forms. These divide and mature through various stages that involve nuclear condensation and extrusion and hemoglobin accumulation. On average, each erythroblast can form about eight reticulocytes. Measurement of the total marrow proerythroblast content[123] and daily reticulocyte production shows that under normal conditions, replicating proerythroblasts largely maintain the reticulocyte pool being renewed from the progenitor compartment at a rate of about 10% per day.[124]

Erythroid Development

Up to this point we have discussed the nondescript progenitors of erythropoiesis without reference to their physical appearance or to the appearance of their differentiated daughter cells. The best evidence to date suggests that hematopoietic progenitors or stem cells look like lymphoblasts,[125-127] and studies of peripheral blood have shown that BFU-E reside in the nonadherent “null” lymphocyte population.[128]

The pathway of erythroid *precursor* differentiation between the development of proerythroblasts and the mature red cell is known as the *erythron* and includes the functioning differentiated precursor cells observed in bone marrow aspirates and biopsies. The morphology of erythroid precursor maturation is well described in several texts and will not be repeated here. The salient features of the morphologic changes during cell development are related to biochemical and kinetic alterations that were reviewed by Granick and Levere[129] and are shown in Figure 1-8. The residence times spent in each morphologic compartment are shown at the bottom of the figure, but the average transit time from proerythroblast to emergence of the reticulocyte into the circulation is approximately 5 days.[130] In acute anemia, the transit time may decrease to as little as 1 or 2 days by means of skipped divisions.[131] The red cells that emerge are macrocytic and may bear surface i antigen and other fetal characteristics because the abbreviated time in the marrow compartment does not permit complete conversion of i antigen to I antigen or acquisition of certain other adult characteristics.[132] The cells also contain excessive burdens of the rubbish that normally accumulates during cell assembly,[133] because less time is available for the cleansing action of cell proteases and nucleases.[134] Thus stress erythropoiesis is associated with circulating Pappenheimer bodies (iron granules), basophilic stippling (ribosomes), Heinz bodies (hemoglobin inclusions), and Howell-Jolly bodies (nuclear remnants).

The kinetics of erythropoiesis can be monitored by the use of radioactive iron and surface scanning. The various ferrokinetic patterns in human diseases are shown in Figure 1-9. The total distribution of erythroid marrow can be determined by scintigraphy using ^{111}InCl bound to transferrin, as shown in Figure 1-10. Both ^{59}Fe kinetics and ^{111}InCl scintigraphy can be useful in the diagnosis of

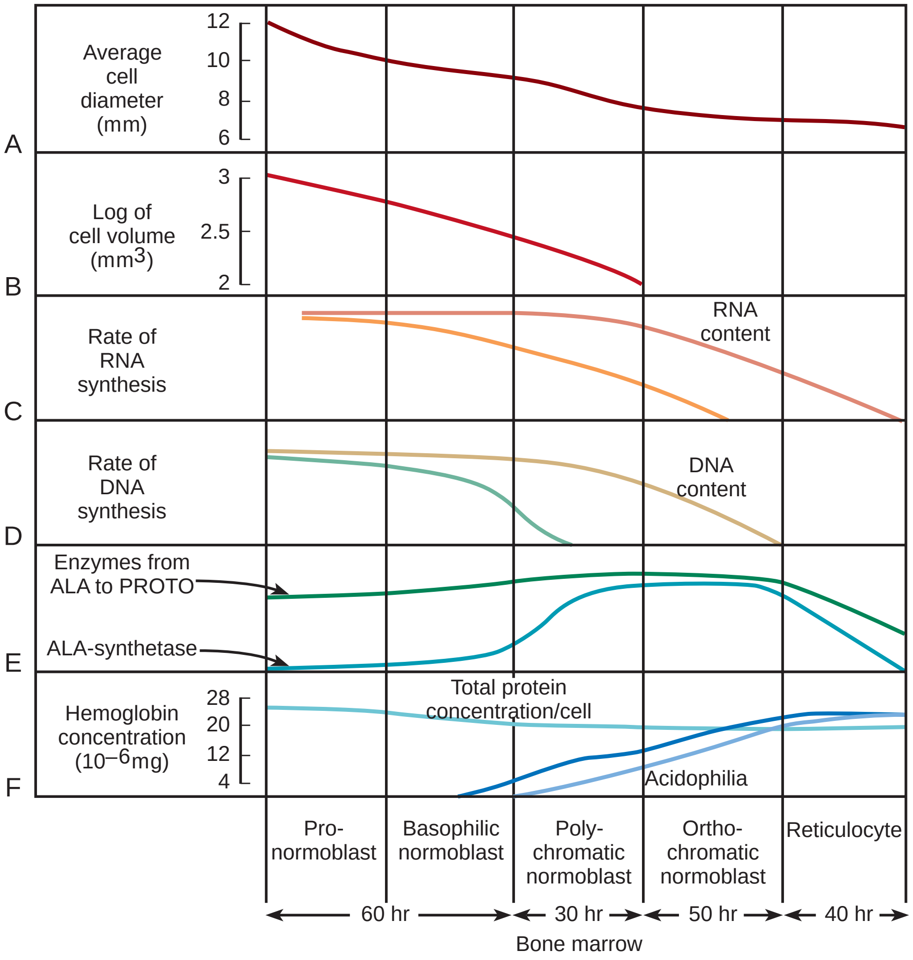

Figure 1-8 Erythroid maturation: alterations in cell size, rates of DNA and RNA synthesis, enzymes involved in heme synthesis, and hemoglobin concentration. Substances listed in the left-hand column are represented by corresponding solid black lines. Unless specified, graphs represent relative values. It will be noted that considerable protein synthesis takes place during the earliest phase. Following this, the nucleolus disappears but mitochondria remain. As the concentration of DNA decreases and the concentration of RNA starts to fall, hemoglobin begins to appear, increasing rapidly in amount. *ALA*, δ-Aminolevulinic acid; *PROTO*, protoporphyrin. *(From Granick S, Levere RD: Heme synthesis in erythroid cells. marrow failure, but these techniques are rarely necessary. The initial uptake of ^{59}Fe in marrow is found primarily in proerythroblasts and early basophilic erythroblasts.[135]

Mouse proerythroblasts; basophilic, polychromatic, and orthochromatic normoblasts; reticulocytes; and mature erythrocytes can be separated on the basis of increasing expression of glycophorin A (Ter119) and loss of expression of CD71.[136] Highly purified populations can be obtained by substituting CD44 for CD71, since there is a thirtyfold loss of expression of CD44 during erythroid maturation compared with a fourfold decrease in CD71 expression.[137]

Neutrophil Production

A model that describes the production and kinetics of neutrophils in humans is shown in Figure 1-11. It is highly compartmentalized. The relatively tiny peripheral blood pool is divided into two components in equilibrium; the circulatory pool (CGP) and the marginating pool (MGP). These pools provide entrance into the tissues. The level of circulating cells is buffered by an immense marrow reserve of identifiable precursors, some of which are in the mitotic compartment and others in a maturing storage compartment. The transit times within each compartment are relatively long, so that a huge reserve remains available. The responses of these compartments to various diseases are detailed in Chapter 22. The kinetics of proliferation of recognizable cell precursors have been studied using labeled precursors of DNA. The so-called labeling indices from which measurements of cell cycle times can be made have served as important approaches to the study of the pharmacology and toxicity of chemotherapy (see Chapter 45).

The final stages of granulocyte production and their release from the marrow are also multifaceted.[138] At least four factors may influence granulocyte egress: the organization and localization of the cells in relation to vascular channels; the development of nuclear and cytoplasmic changes that increase cell deformability; factors that cause cell release; and, finally, the regulation of blood flow through vascular channels in the marrow.

Bone Marrow Examination and Megakaryocytopoiesis

Despite the fact that the morphology of megakaryocyte development is fairly well established (Table 1-1), bone marrow examinations can be of limited value in the various platelet disorders. Bone marrow smears and biopsies provide insufficient data about thrombopoiesis because the final stage of platelet production, extrusion of cytoplasm into the sinusoid and shedding of platelets (to be described later), is not appreciated by these techniques; only the relative numbers of megakaryocytes and

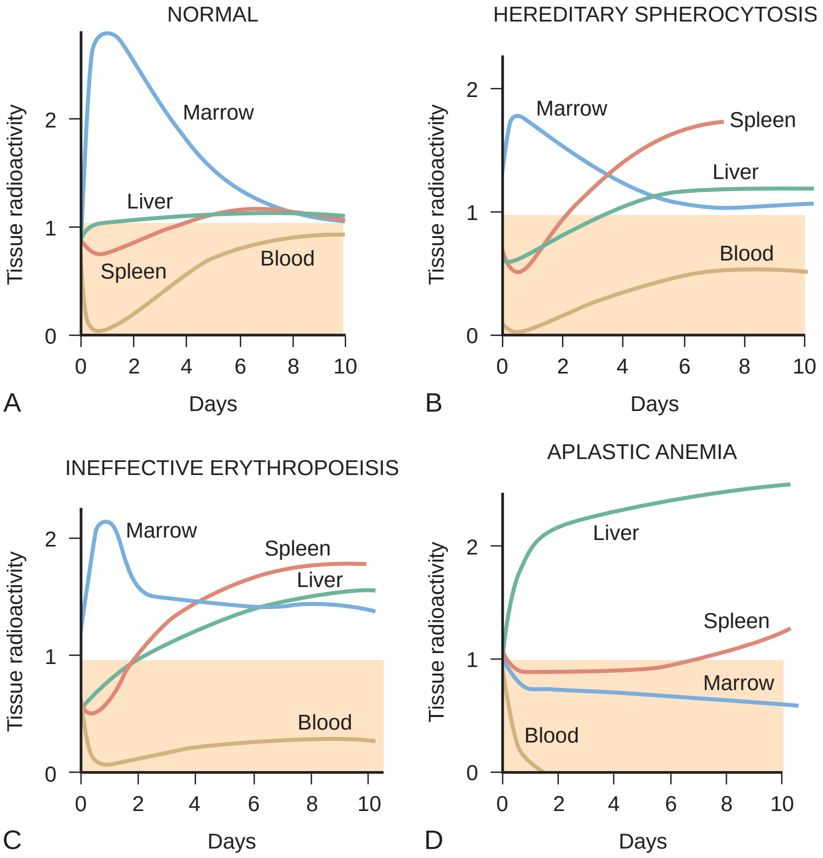

Figure 1-9 Pattern of radioactivity in blood and over sacrum (marrow), liver, and spleen during a ferrokinetic study. Representative data from patients with three different disorders and one normal individual are presented. *(From Finch CA, Dubelbeiss K, Cook JD, et al: Ferrokinetics in man.* Medicine [Baltimore] *49:17–53, 1970.)*

their size and ploidy can be appreciated by routine morphologic methods. It is not surprising that such information is only loosely correlated with platelet production (Fig. 1-12). Furthermore, sampling errors can be responsible for serious misinterpretations. This is a particular hazard in aspirates of neonatal marrow, in which megakaryocytes may be hard to detect whether platelet production is normal or not. Furthermore, megakaryocytes are not evenly distributed in marrow smears. They are more readily found around the edges of the particles, and they may be mistaken for broken cells by the untrained observer. Megakaryocyte nuclei are often found lying free in marrow smears, where they may be erroneously scored as tumor cells. Biopsy sections provide more accurate assessments of megakaryocyte number and distribution than smears, though the latter are usually sufficient (except in neonates) if examined carefully. Biopsies should not be attempted in neonates merely to define megakaryocytes; clinical judgment is a safer tool in these patients.

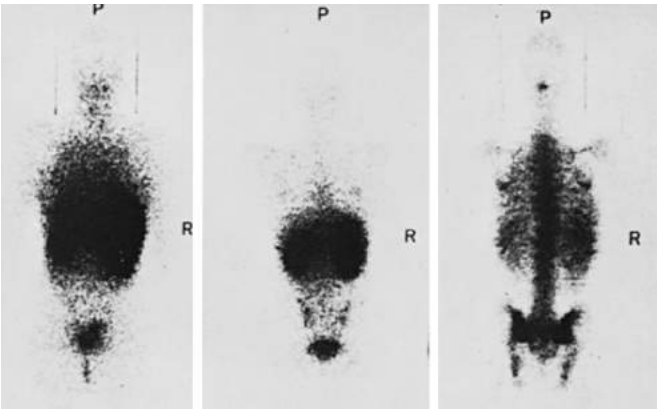

Figure 1-10 Spectrum of scintigraphic patterns in patients with idopathic aplastic anemia. On the left is a scintigram of a patient prior to transplantation with renal activity but no marrow activity. In the middle is a scintigram of a patient with activity in the kidneys and borderline uptake within the marrow. On the right is a normal bone marrow scan in a patient after transplantation. Liver activity is seen in all three patterns, and splenic activity is seen in none. *(From McNeil BJ, Rappeport JM, Nathan DG: Indium chloride scintigraphy: an index of severity in patients with aplastic anaemia.* Br J Haematol *34:599–604, 1976.)*

Examinations of routine marrow smears and biopsies, though instructive, are limited by their two-dimensional views and the thickness of the sections. Megakaryocytes have a peculiar predilection to lie next to the endothelial cell lining of the fronds of developing marrow cells, perhaps because thrombopoietin is produced by these cells. In general, megakaryocytes are too large to squeeze through the sinusoidal meshwork, so they merely push their cytoplasms through the fenestrations. These cytoplasmic structures, called *proplatelets,* serve as microtubule conduits for platelet packaging and release at sinusoids.[139] The protruding cytoplasms form demarcation lines and then shatter into platelets, which are swept into the blood, regulated in part by fibrinogen interacting with platelet integrin αIIbβ3.[140] The megakaryocyte

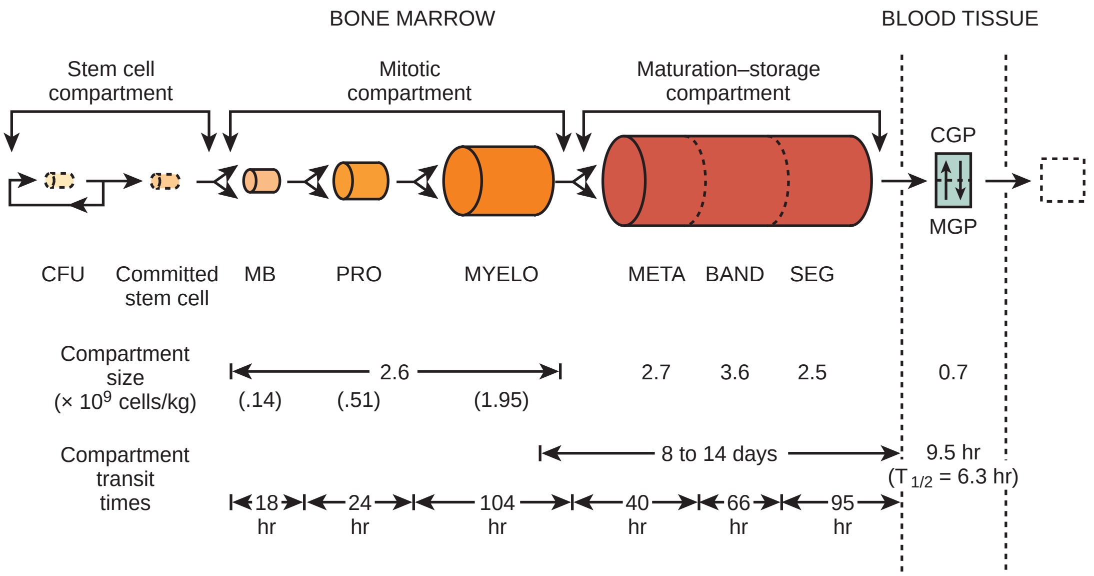

Figure 1-11 Model of the production and kinetics of neutrophils in humans. The marrow and blood compartments have been drawn to show their relative sizes. The compartment transit times, as derived from di-isopropylfluorophosphate ^{32}P studies, are shown on the next to the last line. Values derived from titrated thymidine studies are shown on the last line. *(From Skubitz KM: Neutrophil leukocytes. In: Wintrobe MM, Lee RG, et al, editors:* Clinical hematology, *Philadelphia, 1975, Lea & Febiger, p. 244.)*

nuclei rarely make the transfenestration journey into the sinusoids and thence the blood. If they do, they may be mistakenly interpreted by the unwary microscopist as tumor cells in the blood. Intact or partial megakaryocytes are regularly observed in the blood of patients with marrow-invasive diseases such as certain leukemias, metastatic cancers, granulomatous disorders, and fibrosis.

THE HEMATOPOIETIC GROWTH FACTORS

Since the pioneering work in the early 1960s by Metcalf[116] and Sachs[115] and their coworkers, it has been recognized that normal and leukemic blood progenitor cells can be propagated in culture in the presence of soluble protein growth factors. These factors were originally termed colony-stimulating factors, or CSFs, based on their ability to support the formation of colonies of blood cells by bone marrow cells plated in semisolid medium.[141] During the 1970s and 1980s, it was recognized that there exist multiple types of CSFs based on the different types of blood cells found in the colonies that grew in the presence of the different factors, leading to the hypothesis that the growth and differentiation of different lineages of blood cells are controlled, at least in part, by exposure of progenitor cells to CSFs having different lineage specificities.[141,142] With the molecular cloning of the genes for many of these factors and their receptors during the 1980s and 1990s it became possible to study in detail the structure, function, and biology of the recombinant CSFs as well as the molecular biology of their respective genes.[141-146] This analysis, along with similar work on the regulation of cells in the immune system, led to the realization that there exist a large number of interacting regulatory molecules now generally known as *cytokines* or *lymphohematopoietic cytokines* that together serve to control the hematopoietic and immune systems and to integrate the responses of these systems with those of many other physiologic systems.[144,147-150] These control

TABLE 1-1 Cytologic Characteristics of Megakaryocyte Maturation Stages

Stage	Nuclear Morphology	Cytoplasmic Staining (Wright-Giemsa)	Approximate Size Range	Demarcation Membranes	Granules	Suggested Name
I	Compact (lobed)	Basophilic	6-24 µm	Present by electron microscopy	Few present by electron microscopy	Megakaryoblast
II	Horseshoe	Pink center	14-30 µm	Proliferating to center of cell	Starting to increase	Promegakaryocyte
III	Multilobed	Increasingly more pink than blue	15-56 µm	Extensive but asymmetric	Great numbers	Granular megakaryocyte
IV	Compact but highly lobulated	Wholly eosinophilic	20-50 µm	Evenly distributed	Organized into “platelet field”	Mature megakaryocyte

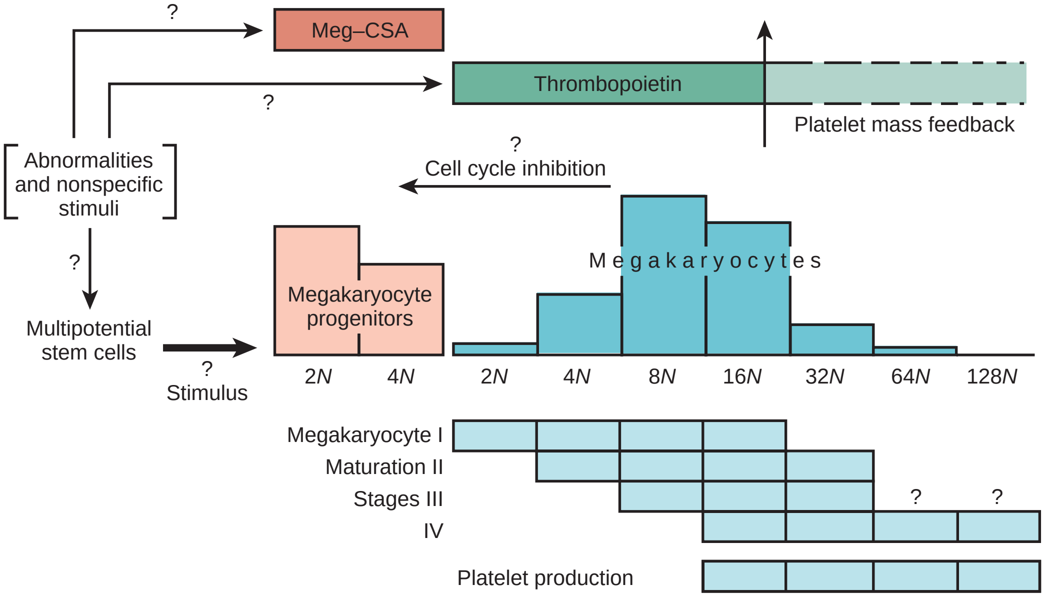

Figure 1-12 Thrombopoiesis. Shown horizontally in the center is the progression from uncommitted multipotential stem cells, through the proliferating progenitors detected in the in vitro clonogenic assays, to the spectrum of maturing megakaryocytes. The relative DNA levels of megakaryocytes and their precursors are given as ploidy values *(N)*, where 2N is a diploid cell. The megakaryocytes are also presented vertically in terms of their maturation stages, ending in platelet shedding; a detailed classification of these stages in given in Table 1-1. The columns show the maturation stages at particular ploidy ranges. Thus 4N megakaryocytes are found at maturation stages I and II. The top row shows a postulated two-level regulatory process with megakaryocyte colony-stimulating activity *(Mega-CSA)* primarily influencing proliferation of progenitors and thrombopoietin required for megakaryocyte ploidy amplification and possibly for maturation. It is not certain that these regulators are completely exclusive in their target cell specificities as shown. Furthermore, no clear distinction is currently possible between the specific or nonspecific control of the two factors. Thrombopoietin production is sensitive to variations in platelet mass, as indicated in the figure; it is assumed that this feedback mechanism operates on the source of thrombopoietin. The progenitors might be controlled by cell cycle inhibition, perhaps as a consequence of normal numbers of megakaryocytes. *(From Williams N, Levine RF: The origin, development, and regulation of megakaryocytes.* Br J Haematol *52:173–180, 1982.)*

molecules serve to regulate the growth, development, differentiation, activation, and trafficking of cells within the hematopoietic and immune systems. With the elucidation of the sequence of most of the human genome in the final years of the 1990s, even more cytokine and growth factor genes have been discovered, providing new insight into how all these systems have evolved with common themes but also providing further challenges to cell biologists in their attempts to understand the functions and interactions of all of the different molecules.

The cytokine gene families that contain at least one member that functions within the hematopoietic or immune system include the lymphohematopoietic cytokines (including many interleukins and CSFs[141,146]); the receptor tyrosine kinase ligand CSF-1,[151] the stem cell factor (SCF) (also known as *steel factor*),[152] and the ligand for the Flk2/Flt3 receptor (FLT-3)[153]; the IL-1 gene family[154]; the chemokines[155]; the tumor necrosis factors[156]; the interferons[157]; the IL-10 gene family[158]; the transforming growth factor β (TGF-β)[159]; and the IL-17 gene family.[160] We will briefly describe these families and the molecules among the family members selected as hematopoietic growth factors (HGFs) for further discussion.

The Lymphohematopoietic Cytokines

For our purposes, the lymphohematopoietic cytokines are defined as the protein ligands for the members of the hematopoietin receptor gene family, also known as the *cytokine receptor class I gene family*.[161] This gene family is characterized by an extracellular domain with pairs of conserved cysteine residues and the distinctive amino acid sequence element Trp-Ser-Xaa-Trp-Ser (WSXWS).[162] These receptors all signal at least partly through the JAK-STAT pathway.[163,164] This rather large family of hematopoietins now includes many interleukins[165] (IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-13, IL-15, IL-21, and IL-23),[146,166,167] granulocye-macrophage colony-stimulating factor (GM-CSF),[141,168] granulocyte colony-stimulating factor (G-CSF),[169] erythropoietin (EPO),[170] thrombopoietin (Tpo),[171] thymic stromal thymopoietin (TSLP),[172-174] leukemia inhibitory factor (LIF),[175] oncostatin M (OSM), cardiotropin 1 (CT-1), and ciliary neurotrophic factor (CNTF).[176] The cytokine receptors on the cell surface signal as multimers, either homomeric or heteromeric, and the family can be further divided into subfamilies based on the molecular composition of their receptor complexes. We will focus on cytokines that have major actions on hematopoietic cells. Those with homodimeric receptors include EPO, Tpo, and G-CSF.[146] A second subgroup comprising GM-CSF, IL-3, and IL-5 in the human system have receptor complexes that share a common subunit known as the *beta common chain* that forms heterodimers with unique cytokine alpha subunits to give selectivity for the respective cytokines.[146] A third group includes IL-6 and IL-11 (as well as LIF, OSM,[177] CNTF, and CT-1, not considered further); all share a common receptor-signaling chain known as *gp130*, with unique chains that provide ligand specificity.[176]

The Receptor Tyrosine Kinase Ligands

Three HGFs, macrophage CSF (M-CSF, also known as *CSF-1*[151]), stem cell factor (SCF),[153,178] and the ligand for FLT3 (FLT3L)[179] have been identified that signal through related receptors, which themselves have tyrosine kinase activity.[153] The receptors for these HGFs are all evolutionarily related, as are the ligands themselves, and each plays an important role in controlling blood cell production.[180,181]

The Interleukin 1 Gene Family

The IL-1[182,183] gene family has grown substantially and now includes at least many IL-1s (IL-1α through IL-1ξ), the IL-1 receptor antagonist (IL-1RA), and IL-18.[154,184] IL-1α, IL-1β, and IL-18 all have potent ability to induce cytokine production (IL-18 particularly interferon gamma (IFN-γ) in combination with IL-12[185]), but the two IL-1s have also been shown to synergize with other HGFs in support of early blood cell proliferation and, therefore, will be considered further here.[186] The functions of the other novel members of the IL-1 gene family are still unknown.

The Chemokines

The chemokines represent a large family of generally small proteins (usually 8 to 12 kDa) readily identifiable by sequence homology, including twin characteristic cysteine residues near the amino termini that separate the family into CC chemokines if the cysteines are adjacent or CX chemokines if they are separated by one residue.[155] Currently, there are more than 50 members of the gene family that have demonstrated important roles in cell trafficking in many systems. The receptor gene family for this cytokine family comprises about 20 members of the G-protein–coupled receptor (GPCR) family. However, their biologic function is not limited to chemotaxis, because several have been shown to effect gene transcription, apoptosis, and cell proliferation. IL-8 is a prominent CX chemokine that regulates neutrophil trafficking and therefore plays a role in inflammatory responses.[155] However, two chemokines, SDF-1[25-28] and macrophage inflammatory protein 1α (MIP-1α)[187] have been reported to inhibit the cycling of very early stem cells and therefore may be important molecules in halting cycling stem cells and returning them to their normal, quiescent state. SDF-1 is clearly very interesting and important in the hematopoietic system as a chemotactic factor for very primitive stem cells, providing possible mechanisms for the homing of cells both as hematopoiesis moves from the fetal liver to the bone marrow and during transplantation of cells in adults.[188]

The Tumor Necrosis Factors

The TNF gene family[161] now includes TNFα, lymphotoxin α and β, CD27Ligand, CD30Ligand, CD40Ligand, FasLigand, TRAIL, and Trance.[150] Many of these molecules are involved in regulating activation and death of various cells, including T lymphocytes and erythroid progenitors. TNFα itself has many biologic activities, particularly in inflammation. However, it is mentioned here because of its potent and important role in promotion of dendritic cell differentiation and activation[189,190] and its capacity to depress hematopoiesis.

The Interferons

The type I interferons (13 species of IFN-α, IFN-β, and IFN-ω) are closely linked on human chromosome 9. The type II interferon gamma (IFN-γ) demonstrates little if any sequence homology with the type I interferons, but the receptors for all of these cytokines are members of cytokine receptor class 2, which is related to but distinct from cytokine receptor class I (HGF receptors) because class 2 receptors lack the distinctive WSXWS sequence.[191] In addition to their antiviral activities, both type I and type II interferons have multiple other regulatory activities with many cell types, including T cells. In the human system, IFN-γ plays a prominent role in polarizing T helper cells toward the type 1 (Th1) phenotype.[150] However, none of these molecules appear to have prominent roles in directly controlling blood cell production and will not be considered further here.[157]

The Transforming Growth Factor Beta Gene Family

The large TGF-β gene family includes TGF-β1, TGF-β2, and TGF-β3; the bone morphogenetic proteins (BMPs) 2 through 16; the growth and differentiation factor (GDF) genes 1 to 10; activin; and inhibin. Like those for many of the other cytokines, the receptors for the TGF-β family members are multimers comprised of two different members of the serine/threonine kinase receptor gene family.[159] Receptors of different ligand specificities are generated by forming these gene products in different combinations. TGF-β1 itself is a very important regulator of cell cycling in many cell systems, including the hematopoietic system, and will be considered here further as a negative regulator of hematopoiesis.[192,193] Mutations in its receptor cause Loeys-Dietz syndrome.[194] The BMPs and GDFs have been implicated in many developmental systems. Interestingly, BMP-4 has been shown to be essential in *Xenopus* species for the embryonic development of HSCs, and it seems at least possible that this molecule might also play a role in mammals in blood cell development during embryogenesis if not in adult hematopoiesis, an area worth following.[194a] However, for our purposes and the sake of simplicity, we will only include TGF-β1 as an HGF.

ACTIONS OF HEMATOPOIETIC GROWTH FACTORS

Predominantly Lineage Specific HGFs: G-CSF, M-CSF, IL-5, TPO, and EPO

Early on, it was recognized that different colony-stimulating factors could selectively support the growth of specific types of hematopoietic colonies.[157] Thus when human bone marrow cells are cultured in semisolid medium in the presence of G-CSF, colonies emerge 7 to 8 days later that consist largely of mature neutrophilic granulocytes and their precursors.[157-169] This finding led to the model that G-CSF, to a large degree, interacts with relatively late hematopoietic progenitors that have already committed to the neutrophil lineage (CFU-G) and thus G-CSF supports their growth and final maturation into functional neutrophils.[169] Similar analysis has revealed that the other major hematopoietic cell lineages have analogous, lineage-specific, late-acting factors and that these molecules frequently serve as important if not primary regulators of the respective pathways. Thus M-CSF supports monocyte/macrophage colony growth and is important in supporting the growth and maturation of monocyte progenitors (CFUs-M)[151]; IL-5 supports eosinophilic granulocyte colony formation and therefore supports the growth and maturation of eosinophil progenitors (CFUs-Eo) as well as activating eosinophils[195,196]; EPO is necessary for the growth and maturation of both earlier (BFU-E) and later (CFU-E) progenitors of the erythroid lineage[170]; and TPO directly supports the growth and maturation of megakaryocyte progenitors (CFUs-meg) and the subsequent production of functional platelets.[171,197]

Although the regulation of the respective blood cell pathways by the lineage-specific HGFs is likely to be their major function, in no case is this lineage specificity absolutely maintained. G-CSF has been found to influence the migration and proliferation of endothelial cells, cells that express high-affinity receptors for this cytokine.[198] IL-5 serves as a growth factor for activated B cells, particularly in the mouse, and affects the type of immunoglobulin secreted by mature B cells.[199] Epo[200] and TPO have been noted to interact with megakaryocyte and erythroid progenitors,[201] respectively. M-CSF appears to be important in trophoblast development.[151] Finally, populations of early HSCs have been found to express receptors for many cytokines; typically, these cells do not respond to single factors but require combinations of factors to trigger them into cycle.[202,203] “Lineage-specific” factors that have been reported to act in various combinations to trigger cycling of early “stem” cells include G-CSF,[204] M-CSF,[205] and TPO,[206] demonstrating that the molecules are not strictly “lineage specific” even within the hematopoietic system. Mice deficient in either the Tpo receptor (*Mpl*) or G-CSF are deficient in levels of all progenitor cells, consistent with the idea that these factors indeed are involved in expansion of early lineage cells.[145] However, when administered in vivo each of these molecules largely influences the growth and development of the expected lineage, so that the designation of lineage specificity seems warranted.

Multilineage Hematopoietic Growth Factors: IL-3 and GM-CSF

Initial analysis of human bone marrow cell cultures grown in the presence of GM-CSF revealed that a variety of different colony types develop over a period of 10 to 14 days.[207] Mature blood cells that could be readily identified included neutrophils, monocytes/macrophages, and eosinophils; this finding led to the designation of the molecule as a “granulocyte-macrophage” colony-stimulating factor, or GM-CSF. In comparison with G-CSF, it was found that it took longer to produce colonies with identifiable neutrophils but the ultimate variety of cell types was greater. This led to a model in which GM-CSF acts on progenitors committed to produce either neutrophils or monocytes (CFU-GM), a precursor to the G-CSF–responsive CFU-G and the M-CSF–responsive CFU-M.[157,207] These later progenitors apparently retain responsiveness to GM-CSF as well because mature monocytes and neutrophils can be observed in cultures supported by GM-CSF alone. That this model is not strictly correct was shown when recombinant GM-CSF was introduced into human bone marrow cultures in the presence of EPO and it was found that this combination of factors was very effective in supporting the development of erythroid colonies (murine GM-CSF is somewhat less effective in this regard).[157,208,209] Thus despite its name, GM-CSF generally interacts with intermediate multilineage progenitors that yield neutrophils, eosinophils, monocytes, erythroid cells, and megakaryocytes (CFU-GEMM). At the time, these activities were similar to those ascribed to IL-3 in the murine system.[210] When human IL-3 was identified, it proved to have abilities to support multilineage colony formation similar to those of human GM-CSF, indicating that it interacts with slightly different but strongly overlapping subsets of progenitors.[211,212] In comparison with GM-CSF, IL-3 is somewhat more effective in supporting multilineage, erythroid, and megakaryocyte colony formation and GM-CSF is slightly more effective with granulocyte and monocyte/macrophage colony formation.[211,212] In serum-free conditions, the ability of IL-3 to support final neutrophil and monocyte maturation is significantly depressed, indicating that the later-acting factors, G-CSF or GM-CSF in the case of neutrophils or M-CSF or GM-CSF in the case of monocytes, are necessary for final end cell production.[213]

In addition to acting slightly earlier than GM-CSF, IL-3 is clearly distinguished in its activity by its ability to support the growth and maturation of mast cells and basophils.[214,215] In the mouse, this was one of the first recognized activities of IL-3,[210] and when IL-3 was first administered to primates, basophilia was one of the most prominent findings.[215,216] Thus IL-3 appears to be capable of supporting the growth and development of basophil and mast cell progenitors. In the human system, both IL-3 and GM-CSF can support the development and differentiation of dendritic cells of either myeloid or lymphoid origin, especially in combination with SCF, FLT3L, and TNF.[217-219]

Other Interleukins

IL-4 in mice and humans has been reported to support multilineage colony formation, including colonies that contain cells from the erythroid, megakaryocytic, neutrophilic, and monocytic lineages.[220-222] IL-4 in the mouse supports mast cell growth and therefore shares many activities with IL-3.[199] However, IL-4 plays very important roles in the development and maturation of T cells and B cells,[199,222,223] particularly in the polarization of cytokine production by helper T cells toward the type 2 (Th2) response.[224] Therefore, on balance IL-4 is likely to be more important in controlling immune cell development and function and will not be discussed further here. IL-9 in both the murine and human systems has been shown to enhance erythroid colony formation in the presence of Epo[225] and appears to play a role in T-cell and B-cell development as well.[226] More recently, IL-9 has been shown to have some effects on the growth and activation of mast cells and may play some role in the pathology of asthma.[227]

Early-Acting Hematopoietic Growth Factors: Stem Cell Factor and Flt3 Ligand

Stem cell factor (SCF)[152,153,178] and FLT3 ligand (FLT3L),[179,228,229] both receptor tyrosine kinase ligands, interact with a variety of hematopoietic progenitor cells, perhaps most importantly with very early stem cell populations. SCF also plays an important role in melanocyte growth and development, which is reflected in the coat color effects of mutations in SCF or its receptor, KIT.[152] Genetic analysis of mice clearly showed that mice defective in either SCF *(Sl* mice*)* or in *Kit (W* mice*)* have serious hematopoietic (and many other) defects, including macrocytic anemia, mast cell deficiencies, and deficiencies in the stem cell compartment (reviewed in reference 152). These early studies had already indicated the critical importance of SCF in the survival and development of stem cells. Mutations in the human *KIT* gene lead to a similar phenotype in melanocyte development in humans known as the *piebald mutation;* however, these individuals do not have any hematologic problems, probably because severe mutations in this locus are likely to be lethal.[230] In vitro, the activities of SCF are generally most evident when combined with other HGFs; the proliferative activity of SCF with hematopoietic cells in culture as a single factor is minimal.[152] In fact, culture of murine bone marrow cells in SCF alone ultimately yields largely mast cells.[231] However, SCF acts synergistically to enhance the activities of most of the other HGFs in culture and is particularly effective when combined with HGFs such as IL-3, IL-1, or IL-11 at promoting the expansion of "blastlike cells" that retain considerable potential for yielding multilineage colonies in secondary culture.[232-234] These colonies, when replated under conditions that support B-lymphocyte development or when transplanted into animals also yield B and T lymphocytes, indicating that SCF-responsive cells include primitive stem cells with both lymphoid and myeloid potential.[235,236] SCF has also been implicated in combination with IL-2 or IL-7 in early stages of T-cell development in the thymus,[237] with IL-7 in pre–B-cell growth,[238] and with IL-7 in enhancing NK cell responsiveness to IL-2.[152] However, the fact that none of these lineages are dramatically affected in *W* or *Sl* mice indicates that SCF-independent mechanisms can compensate in these systems.

SCF,[239] M-CSF,[240] and FLT3LG[181] are all expressed as both membrane-bound and soluble forms. In the case of SCF, expression of membrane-bound forms of the molecule in the marrow microenvironment provides a nice model for how this growth factor might act locally. Indeed, cell lines that express membrane-associated SCF exclusively are much more effective in supporting long-term hematopoiesis in vitro than cell lines that produce soluble forms of the molecule exclusively.[239] This interaction of membrane-associated SCF with KIT provides one mechanism for the adherence of hematopoietic cells to stroma; binding of human megakaryocytes to fibroblasts can be blocked by antibodies to KIT.[241] Finally, if membrane-associated forms of SCF are present in which the cytoplasmic domain is essentially missing, the result is male but not female sterility, suggesting that the cytoplasmic domain may have an as yet undetermined important biologic function.[152,242]

As shown by the early genetic studies and confirmed through analysis of the recombinant protein, SCF is not specific for the hematopoietic system. It is an important growth factor for melanocytes and primordial germ cells, and it appears to play a role in development of the nervous system, perhaps as a neuronal guidance factor, although it has been difficult to demonstrate neurologic defects in *W* or *Sl* mice[152] other than the fact that the mice are severely constipated due to SCF dependence of intestinal Cajal cells.[243]

The FLT3 receptor tyrosine kinase was originally identified as a novel receptor present in HSCs; with human marrow, the expression is largely limited to the CD34+ cell population.[244-246] FLT3L alone yields low numbers of CFU-GM colonies from human bone marrow but acts synergistically with other cytokines, including IL-3, GM-CSF, EPO, and SCF, to yield enhanced colony formation, both in terms of size and numbers of colonies.[228,247,248] The synergy observed between FLT3L and the other HGFs is comparable to that observed with SCF in similar systems, with the exception that FLT3L has little effect on BFU-E.[229] Multifactor combinations with SCF have been used for expansion of colony-forming cells in long-term cultures; FLT3L has effects comparable to those of SCF when combined with IL-1, IL-3, IL-6, and EPO in 4-week cultures.[249,250] Like SCF, FLT3L in combination with other cytokines such as GM-CSF supports dendritic cell development from CD34+ bone marrow cells.[217] In contrast to SCF, FLT3L does not support the growth and development of mast cells.[228,247] Despite this overlap in bioactivities, mice in which the Flt3 receptor tyrosine kinase has been disrupted appear to have normal hematopoiesis, with the only detectable defects observed within the B-lymphocyte lineage.[251] However, mice in which both the *Kit* and *Flt3* receptor tyrosine kinase genes have been disrupted display more severe hematologic complications than mice with mutation of only one of these genes, suggesting that the two pathways can to some degree compensate for one another.[251] The importance of FLT3L in B-cell growth has also been shown with cultures of primitive B-cell progenitors (CD43+, B220^{low}) in combination with either IL-7 or SCF.[252] Altogether, these findings argue for an important role for FLT3L in hematopoiesis.

Other Stem Cell Factors: Wnt, Jagged, BMP, and Angiopoietin-like Growth Factors

Several new growth factors have been shown to regulate HSC production during embryogenesis as well as adulthood. The wnt family of factors regulates stem cell homeostasis.[253-259] Overexpression of wnt 3A led to a threefold expansion of HSCs. This is the first time that stem cell number was actually increased in a competitive repopulation assay. In separate experiments, overexpression of β-catenin led to an expansion of HSCs, and sorting by activated β-catenin in HSCs based on a wnt reporter line that turned cells green when wnt was activated demonstrated HSC activity. Further studies in chronic myeloid leukemia (CML) demonstrated that wnt activation was present in leukemia.[260] These studies demonstrated that wnt activity could drive HSC production; however, other experiments have demonstrated that the knockout of β-catenin within the HSCs is not required for stem cell homeostasis.[261] Two papers demonstrated that a constitutively activated β-catenin in HSCs leads to aplastic anemia.[262,263] The activation of the wnt pathway may not be necessary for stem cell homeostasis, but it may be sufficient to drive the HSCs to produce more self-renewal cell divisions.

The wnt pathway clearly interfaces with HSC production. It is possible that pulses of wnt will have different activity than a constitutively active wnt signal. In addition, redundancy within the marrow space among other signaling pathways, including the notch and BMP pathways, has left the stem cell compartment with significant chances of survival. Wnt acts through canonical and noncanonical pathways. In the former case this leads to activation of β-catenin to the nucleus through the complex involving adenomatous polyposis coli (APC) and β-catenin. In the latter, there is stem cell activation by the Rho GTPases. Wnt activation acts at multiple places during hematopoiesis, at the stem cell level, at the pre-B-cell level, and at multiple places in T-cell development. Wnts bind to canonical frizzled receptors and activate a signaling pathway. An antagonist wnt signal, wnt 5a, suppresses B-cell proliferation and may act to suppress stem cell homeostasis. Other wnts have been found to regulate hematopoiesis, including wnt 2b and wnt 10b for human bone marrow CD34+ cells.

The notch pathway has been shown to regulate HSC production based on retroviral transduction of hematopoietic cells.[264,265] This expands the population of HSCs significantly. Notch works through a ligand receptor interaction in which deltas and jaggeds are presented on the stem cell niche. In general, jagged2 is thought to be the predominant notch ligand in the marrow and is presented by the osteoblast. Modulation of jagged2 leads to an expansion of HSC production. The notch pathway has been put into a genetic pathway with runx1, based on the zebrafish mutant mindbomb.[266] Mindbomb mutants have no notch signaling due to a defect in an E3 ubiquitin ligase that promotes ligand recycling. This mutant lacks HSCs during development, and overexpression of runx1 rescues hematopoiesis. A pulse of notch signaling has been shown to expand HSCs in the zebrafish system. Furthermore, the runx1 rescue of notch 1 mutant was demonstrated in the mouse system and it was also shown that GATA2 was a target of the notch pathway.[267,268] Modulation of wnt and notch demonstrates synergy of wnt 3a and activation of the notch pathway. It is possible to activate wnt pathways using the chemical called *BIO drug*, which is an inhibitor of glycogen synthase kinase 3beta GSK-3β. This modulation of the wnt and notch pathways represents a significant role in stem cell homeostasis.

The bone morphogenetic protein family has been demonstrated to induce HSC production in the *Xenopus* and zebrafish systems.[194a,270-276] This leads to an expansion of the erythroid blood islands during early development. Interestingly, a dominant-negative version of BMP activated later in development leads to enhanced erythropoiesis, demonstrating two independent effects of BMP regulation of HSC differentiation and proliferation. Furthermore, BMP has recently been shown to expand HSC production in the aorta-gonads-mesonephros region. BMP was shown to expand or maintain HSC production in human embryonic stem cells and functions as a key regulator of stress-induced erythropoiesis.[277] BMP also regulates the stem cell niche. It is unclear how BMP and the notch and wnt pathways interact.

Angiopoietin-related proteins are potent activators of HSC production.[278] Thus angiopoietin-like 2 and angiopoietin-like 3 were shown to lead to a twentyfold or thirtyfold expansion of long-term HSCs when they were cultured for 10 days in the presence of the ligands. This was demonstrated by a limiting-dilution competitive repopulation assay. Thus angiopoietin-like genes must also participate in the stem cell niche. Another growth factor glycoprotein called *osteopontin* was also involved in stem cell homeostasis; it negatively regulates the stem cell pools.[279,280] A number of factors, including TGF-β1, have a negative regulation as well. Ligands produced by the stem cells themselves may also regulate stem cell homeostasis.

Synergistic Factors: IL-1, IL-6, and IL-11

Early in the 1980s, activities were identified that had the ability to enhance hematopoietic colony formation supported by other HGFs, particularly with early progenitor cells. One activity, designated hematopoietin 1, was subsequently purified and discovered to be IL-1.[205] In this fashion, IL-1 was recognized as having little ability on its own to stimulate hematopoietic colony formation but was able to act in synergy with other HGFs, notably IL-3, in increasing both the frequency of colony formation and the numbers of cells per colony.[186] Subsequent to the discovery of the synergistic activity of IL-1, numerous other cytokines have emerged with similar activity, including IL-6,[281] IL-11,[282] leukemia inhibitory factor (LIF),[283] and IL-12.[284] Of these, IL-6, IL-11, and LIF all signal through a common signal-transducing molecule, the gp130 component of the IL-6 receptor.[285] Because these molecules are likely to behave similarly in most systems and because IL-6 and IL-11 have been the most thoroughly studied, we will limit our discussion to these two members of this family. IL-12, which signals through a distinct but perhaps similar pathway to gp130,[286] has interesting effects in combinations with other cytokines[284] but appears to be more important in regulating the development and activities of T and NK cells[287,288] and will therefore not be discussed further here.

The effects of IL-1 on hematopoiesis have been highly complicated by the fact that this cytokine is a potent inducer of secondary cytokine production, frequently by accessory cells in the culture.[289] The induction of other growth factors, notably IL-6, G-CSF, GM-CSF, and IL-11, is likely to contribute to the activity of IL-1 as a synergistic factor in hematopoietic colony formation. Nevertheless, combinations of IL-1 with other factors in cultures of highly purified hematopoietic cells typically yield synergistic effects, suggesting that at least some of the effects are direct.[290,291] However, even with highly purified hematopoietic progenitor cell populations, the effects of IL-1 can be indirect. For example, Rodrigues and colleagues[292] have reported that IL-1 can prevent apoptotic death of CD34+ lin– human bone marrow cells but the effect is largely abrogated by antibodies to GM-CSF, suggesting that some progenitor cells in the population can produce their own GM-CSF. Thus the survival effect of IL-1 in some systems may also be indirectly mediated by induction of GM-CSF expression in CD34+ lin– bone marrow cells themselves.

IL-6 is an extremely pleiotropic cytokine with important effects on the growth and differentiation of T and B cells, on the induction of the hepatic acute-phase response, and on the enhancement of the proliferation of hematopoietic progenitor cells.[244] IL-6 signaling, mediated by two members of the hematopoietin receptor gene family, IL-6R[293] and gp130,[294] was the first example of signaling through a commonly shared receptor subunit, gp130, which now is known to be involved in the signaling of LIF, IL-11, oncostatin M (OSM), ciliary neurotrophic factor (CNTF), and cardiotrophin-1 (CT-1).[285,295] Because most cells express gp130, the expression of other receptor components such as IL-6R or IL-11R generally determines whether or not a cell will respond to one of these family members; cells that express receptors for multiple members of this cytokine subgroup generally exhibit identical or nearly identical responses to each member whose receptor component is expressed by the cell.[176,285,296]

IL-6 has little if any ability to support colony formation on its own but can enhance colony formation supported by other HGFs, particularly IL-3 and SCF.[232,281] This effect was most prominent using bone marrow cells from mice isolated for 2 days following treatment with 5-FU, a drug that enriches for primitive progenitors by selectively killing later, actively cycling cells in the bone marrow.[202] Bone marrow cells treated in this fashion generally yield significant numbers of colonies only when plated in the presence of multiple HGFs. In this system, IL-6 was found to enhance colony formation supported by IL-3 or SCF. These early cells are typically quiescent in the G_0 phase of the growth cycle, and combined effects of cytokines, such as IL-3 and IL-6, are required to push them into active cycling.[202] Similar effects have been observed with cultures of purified early human hematopoietic progenitor cells.[297]

As noted above, the IL-11 receptor complex employs the IL-6 gp130 signal-transducing system. Thus IL-11 and IL-6 appear to have somewhat overlapping biologic activities.[298] In general, IL-6 has proved to have more effects on T and B cells than IL-11[244,299] and similar effects in the hepatic acute-phase response[300] and on osteoclast formation,[301] but IL-11 is somewhat more potent in megakaryocytopoiesis.[302] Like IL-6, the effects of IL-11 in hematopoietic cultures are largely observed only in combination with other factors. IL-11 in combination with SCF or FLT3L has proved to be very effective in supporting the growth of primitive hematopoietic progenitors.[248] Soon after its discovery, IL-11 was shown to have important effects on the growth and development of megakaryocyte progenitors.[299,302,303] Again, in this system, IL-11 had little effect on colony formation on its own but was found to act in synergy with IL-3, SCF, or, more recently, TPO in supporting CFU-meg colony formation.[304] Its clinical use in thrombocytopenic states has been disappointing.

Negative Regulator of Hematopoiesis: Transforming Growth Factor Beta

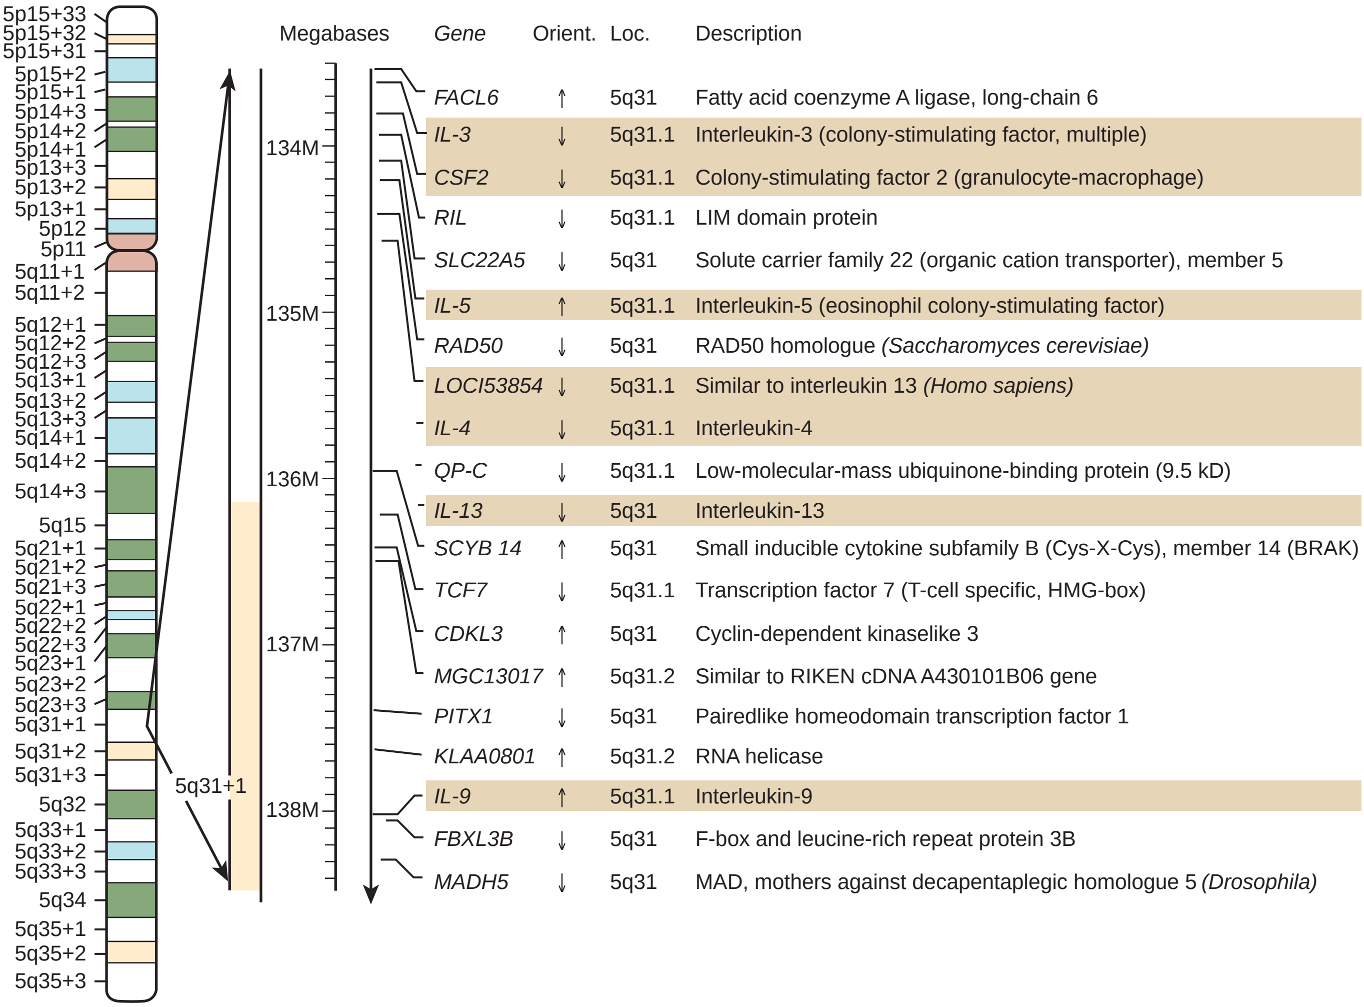
A variety of cytokines have been reported to reversibly inhibit cycling of early hematopoietic cells, including the chemokines SDF-1,[208] MIP-1α,[187] and TGF-β, perhaps the most potent of all.[305-307] Very interestingly, when individual early cells were plated in wells, either antibody to TGF-β1 or an antisense oligonucleotide to the mRNA for this factor could trigger the release of the cells from quiescence in the presence of appropriate combinations of early-acting cytokines, which by themselves alone failed to trigger the cycling of the cells.[306,307]

MOLECULAR BIOLOGY OF HEMATOPOIETIC GROWTH FACTORS

Genomic Analysis of the Cytokine and Cytokine Receptor Genes

With analysis of the human genome, several common themes and relationships have emerged from the different types of cytokine/growth factor and receptor genes. First, as we have already noted, most of the cytokines and their receptors exist as members of distinct, evolutionarily related gene families; examples of a single cytokine or growth factor gene with no relatives are rare. Similarly, the receptors also fall into gene families. Thus a relatively small number of primordial growth factor/cytokine genes were duplicated many times, forming families of genes that evolved into serving regulatory functions for many different systems. Interestingly, in most cases, each of the individual cytokines of a particular gene family use members of a single receptor gene family. For example, all of the chemokines use G-coupled protein receptors as their signaling/recognition molecules,[155] and all of the members of the TGF-β gene family use different combinations of the serine/threonine kinase receptors as their recognition and signaling molecules.[159] All of these receptor-ligand pairs must have evolved in concert as they were selected to control different cellular processes.

Despite the obvious gene duplications that have occurred in all of these gene families, there is no absolute rule as to how the genes are arranged today. In some cases, the related genes are still closely linked in tandem in the genome, as is the case for the IL-3 and GM-CSF genes on chromosome 5 at 5q31.1 (Fig. 1-13). In this case, another duo of related genes, IL-4 and IL-13, are very closely linked to one another but are slightly more separated from the IL-3/GM-CSF cluster.



Gene	Orient.	Loc.	Description
FACL6	↑	5q31	Fatty acid coenzyme A ligase, long-chain 6
IL-3	↓	5q31.1	Interleukin-3 (colony-stimulating factor, multiple)
CSF2	↓	5q31.1	Colony-stimulating factor 2 (granulocyte-macrophage)
RIL	↓	5q31.1	LIM domain protein
SLC22A5	↓	5q31	Solute carrier family 22 (organic cation transporter), member 5
IL-5	↑	5q31.1	Interleukin-5 (eosinophil colony-stimulating factor)
RAD50	↓	5q31	RAD50 homologue *(Saccharomyces cerevisiae)*
LOCI53854	↓	5q31.1	Similar to interleukin 13 *(Homo sapiens)*
IL-4	↓	5q31.1	Interleukin-4
QP-C	↓	5q31.1	Low-molecular-mass ubiquinone-binding protein (9.5 kD)
IL-13	↓	5q31	Interleukin-13
SCYB 14	↑	5q31	Small inducible cytokine subfamily B (Cys-X-Cys), member 14 (BRAK)
TCF7	↓	5q31.1	Transcription factor 7 (T-cell specific, HMG-box)
CDKL3	↑	5q31	Cyclin-dependent kinaselike 3
MGC13017	↑	5q31.2	Similar to RIKEN cDNA A430101B06 gene
PITX1	↓	5q31	Pairedlike homeodomain transcription factor 1
KLAA0801	↑	5q31.2	RNA helicase
IL-9	↑	5q31.1	Interleukin-9
FBXL3B	↓	5q31	F-box and leucine-rich repeat protein 3B
MADH5	↓	5q31	MAD, mothers against decapentaplegic homologue 5 *(Drosophila)*

Figure 1-13 Cytokine gene cluster at 5q31.1. The region from chromosome 5, comprising five megabases of DNA sequence, is expanded as shown with the structures of the individual genes with GenBank notations, descriptions, and gene orientations as indicated. The region contains approximately 115 genes, 21 of which are illustrated. The data were collected and assembled from the National Center for Biotechnology Information database.

Structures of the Hematopoietic Growth Factor Proteins

The availability of the cDNAs for the individual cytokines allowed for the rapid determination of their primary amino acid sequence, for their expression in quantities large enough for direct x-ray determination of their crystal structures, and, more broadly, for predicting structures based on those of proteins related even distantly by sequence. One of the clear results of this analysis of the structures of the different cytokines was the realization that, despite generally low conservation of amino acid sequence, many of the lymphohematopoietic cytokines are distantly related in evolution. Most of the lymphohematopoietic cytokines are believed to assume a tightly packed, antiparallel, four—α-helix–bundled structure with either short or long helical bundles.[146,150] Lymphohematopoietins having the short helical bundle structure include IL-2, IL-3, IL-4, IL-5, IL-7, IL-9, IL-13, IL-15, and GM-CSF; cytokines having the long helical structure include the gp130 signaling proteins IL-6, IL-11, LIF, and OSM; IL-12p35; and the homodimeric receptor signaling proteins EPO, TPO, and G-CSF.[146,197,308]

Sequence and structural information suggest that the cytokines with the long helical bundle structure are all distantly related in evolution. Members of the IL-6 subfamily, including IL-6, IL-11, and G-CSF, show rather modest sequence similarity but display common gene organization and certain structural features that suggest evolutionary relatedness.[149,308,309] Sequence alignments of IL-6 and G-CSF show conservation of cysteine residues.[310] Interestingly, a cytokine identified in the chicken, myelomonocytic growth factor (MGF),[311] displays sequence similarities with G-CSF and IL-6, which suggests that all three are derived from a common ancestral gene. Erythropoietin shows some structural features similar to those of growth hormone and to G-CSF but at a very low level.[308] In contrast, the amino-terminal half of TPO shows strong sequence similarity with EPO, whereas the carboxy-terminal half is unrelated to any known protein.[312-314] The four-helical-bundle structure of EPO is clearly related to the amino-terminal, helically structured portion of TPO, whereas the additional domain of TPO, which is heavily glycosylated, may serve to increase the

TABLE 1-2 Genetic Defects in Receptors or Signaling Proteins

A. Human Mutations

Gene	Mutation	Phenotype	Reference
IL2Rγc	Deletion	X-linked severe combined immunodeficiency (SCID)	909
JAK3	Deletion	SCID	910
GCSFR	C-terminal deletion	Kostmann disease developing leukemia	419
EPOR	C-terminal deletion	benign erythrocytosis	911

B. Nonhuman Mutations

Species	Gene	Name	Phenotype	Reference
Mouse	*Kit*	White-spotting	Macrocytic anemia, mast cell deficiency, lack of pigmentation, sterile	520, 519, 564
	Sl	Steel	Macrocytic anemia, mast cell deficiency, lack of pigmentation, sterile	520, 519, 564
	Csf1	Microphthalmia	Osteopetrosis due to decreased osteoclast function	342
	Hcp	Motheaten	Immunodeficiency, autoimmune disease, increased sensitivity to EPO	487
Drosophila	JAK homologue	Hopscotch	TumL allele, gain-of-function mutation that causes leukemia	912, 913

C. Targeted Disruption in Murine Embryonic Stem Cells

Gene	Phenotype	Reference
Il-6	Decreased CFU-S and stem cell function	329
Gmcsf	Hematopoiesis normal; progressive accumulation of pulmonary surfactant	340, 341
Gcsf	Neutrophils 25% normal; impaired response to *Listeria monocytogenes* infection	317
Epo	Embryonic lethal; failure of definitive erythropoiesis	327
Epor	Embryonic lethal; failure of definitive erythropoiesis	327
Tpor (Mpl)	Platelets 15% to 20% normal	322
IL-3/-5/GMRβc	Similar to *Gmcsf*$^{-/-}$ mice; also low eosinophils and impaired eosinophil response to *N. brasiliensis*	712
Vav	Not required for hematopoiesis	914

serum half-life of the molecule. Both of these family members are believed to act as monomers.

The ligands for the receptor tyrosine kinase gene family members, SCF, FLT3L, and M-CSF, share many structural similarities.[152,181,315] All three contain transmembrane domains and are initially synthesized as homodimeric integral membrane proteins. Although the membrane-bound forms are functional, dimeric soluble forms that also display biologic activity are released from the cell by proteolysis. The extracellular domains display low but significant sequence similarity, including conservation of the positions of the cysteine residues involved in disulfide bridge formation.[181] Modeling of these extracellular domains indicates that they, too, are likely to form four α-helix–bundled structures tethered to the membrane through variable spacer domains, with dimerization through a cysteine located in the spacer domain.[146,180,181]

Hematopoietic Growth Factor Gene Disruptions

Hematopoietin Receptor Ligands

G-CSF Gene. The combination of technology for disrupting genes in cultured mammalian cells has led to methodology for studying gene function in vivo (mutants related to HGFs are summarized in Table 1-2).[316] Using this approach, Lieschke and associates[317] were able to generate mice with both copies of the *G-CSF* gene disrupted. These animals develop normally but as adults display a 70% to 80% reduction in levels of circulating neutrophils, a 50% reduction in the numbers of progenitors in all lineages, and impaired resistance to challenge to infections with *Listeria monocytogenes*. These findings, which are in agreement with earlier observations by Hammond and colleagues[318] in dogs that had developed cross-reacting antibodies to canine G-CSF, demonstrate the central role for G-CSF in controlling neutrophil levels. However, the decline in all populations of progenitors is consistent with a role for G-CSF prior to commitment to the neutrophil lineage, perhaps at the early stem cell stage.[319,320]

Erythropoietin and Thrombopoietin. The *TPO* and *EPO* genes have clearly evolved from a common ancestor; at some point the extra protein-coding region found in the final coding exon of the *TPO* gene was either removed (in the case of the *EPO* gene) or added (in the case of the *TPO* gene) following the early duplication event.

Mice with deletion of either the *Tpo* or *Mpl* gene have been described.[321,322] Although these animals develop normally and do not display signficant abnormalities in bleeding times, they do have only 15% to 20% of the normal levels of circulating platelets. This result implies that TPO is very important for maintaining circulating levels of platelets but that other cytokines might have some capacity to generate platelets at low levels. TPO has also been shown to have effects on stem cell homeostasis.[323-326] In the case of *Epo*, gene disruption results in embryonic lethality due to failure of fetal liver erythropoiesis.[327]

IL-6–gp130 Complex Ligands: IL-6 and IL-11. Animals that have been engineered to lack the *IL-6* gene develop normally but display significant deficiencies in various immune and inflammatory responses.[328] The hepatic acute-phase response in these animals is severely compromised after tissue damage but only moderately in response to lipopolysaccharide (LPS) The effects of disruption of the *IL-6* gene on normal hematopoiesis are relatively minor; a slight decrease in peripheral blood leukocyte counts, a 10% reduction in bone marrow cellularity, a 50% reduction in CFU-S_{d12}, and a fourfold to fivefold reduction of pre–CFU-S.[329]

GM-CSFR Complex Ligands: IL-3, GM-CSF, and IL-5. The genes for each of these proteins comprise approximately 3000 base pairs divided among four exons (GM-CSF[330,331] and IL-5[199,332]) or five exons (IL-3[331,333]) with somewhat similar structures. All of these genes have been localized to the long arm of chromosome 5 at 5q31.1,[334] a region commonly disrupted or deleted in patients with various malignant myeloid neoplasms.[335] This region also contains the genes for other important cytokines, including IL-4, IL-9, IL-12p40, and IL-13.[334-336] Detailed mapping of the region has demonstrated that several of these genes are very closely linked: the *GM-CSF* and *IL-3* genes are tandemly arrayed within 9 kb of one another;[337] the *IL-4* and *IL-13* genes are separated by only 12.5 kb.[334] This clustering of molecules with similar structures and functions, including the sharing of receptor components in the case of the *GM-CSF*, *IL-3*, and *IL-5* genes,[338,339] provides further strong support for the evolutionary relatedness of their respective genes.

Mice with homozygous disruption of the *GM-CSF* gene develop normally and display neither numerical defects in the levels of circulating granulocytes or monocytes nor defects in the levels of CFU-GM progenitors in marrow or spleen.[340,341] These animals exhibit alveolar proteinosis with surfactant accumulation in the lungs based on defective aveolar macrophage function. GM-CSF plays an irreplaceable role in the function and development of certain macrophage populations, but any function played by this cytokine in controlling basal or stimulated production of granulocytes or monocytes can be replaced by other factors.

To evaluate the role of the entire IL-3/GM-CSF/IL-5 complex, Nishinakamura and coworkers[341a] engineered a mouse lacking the beta-c receptor component shared by all three cytokines as well as a disruption in the *IL-3* gene. Mice lacking beta-c show a pulmonary alveolar proteinosis-like disease and reduced numbers of peripheral eosinophils, which are explained by the lack of GM-CSF and IL-5 functions, respectively. Combination with the *IL-3* gene disruption showed no further abnormalities in hematopoiesis, demonstrating that the entire IL-3/GM-CSF/IL-5 axis is dispensable for hematopoiesis both in normal and stressed mice.

Receptor Tyrosine Kinase Ligands: M-CSF, Stem Cell Factor, and FLT3 Ligand. The *M-CSF*, *SCF*, and *FLT3* genes are evolutionarily related.[180,181] The gene for M-CSF proved to be defective in the spontaneous mutant osteopetrosis (*op/op*).[342] Female *op/op* mice are infertile, confirming the role of M-CSF in the biology of the pregnant uterus.[343] They also have a severe deficiency in the ability to develop osteoclasts derived from the monocytic lineage, resulting in the development of osteopetrosis and the failure to develop teeth.[344] The animals do develop some macrophage populations, indicating that M-CSF is important in many but not all macrophage-related lineages. The observation that some of the defects in the *op/op* mouse are corrected as the animals mature has led to speculation that alternative splicing of the mutant M-CSF transcript can lead to production of some functional M-CSF.[345] The OP9 stromal cells are often used in the expansion of stem cells, showing that M-CSF suppresses stem cell growth.[346]

Naturally occurring mutations in the SCF locus (*Sl*) or in the receptor for SCF, Kit (*W*), result in profound effects on many stages of hematopoiesis, most notably in the stem cell, erythroid, and mast cell compartments.[152] These studies have clearly demonstrated the central role of SCF in controlling hematopoietic cell function. Interestingly, disruption of the *Flt3* receptor gene has relatively minor effects on hematopoiesis, the most notable being somewhat depressed levels of B-lymphocyte precursors.[251] However, mice with disruption of both the *Kit* and *Flt3* receptor tyrosine kinase genes display more severe hematologic complications than mice with a mutation of only one of these genes,[251] suggesting that the two factors do, at some level, complement one another in vivo.

Hematopoietic Growth Factor Genes: Regulation of Expression

Expression of Hematopoietic Growth Factors by Monocytes/Macrophages and Dendritic Cells: G-CSF, M-CSF, GM-CSF, IL-6, and SCF

Monocytes/macrophages and related cells, including dendritic cells, Kupfer cells in the liver, and Langerhans cells in the skin, are key cells that serve many important functions in regulating the immune system.[347] Among the functions performed by these cells is the production of many cytokines, including TNF,[348] IL-1,[185] G-CSF,[169] M-CSF,[348] GM-CSF,[142] IL-6,[244] and IL-12,[347] in response to various stimuli, including LPS,[347,348] IL-1, IL-3,[349] GM-CSF,[350] and M-CSF.[351] Other cytokines, including IL-4,[352] IL-10,[353] and IL-11,[354] downregulate monocyte production of many of these cytokines. Several of the cytokines, including IL-18,[185] various members of the *IL-17* gene family,[355] and IL-23,[167] are playing important roles in controlling cytokine production by monocytes and macrophages.

All of these interactions are key components of the interactions between T cells and monocytes in determining the nature and direction of the immune response. Different regulators have been found to induce different subsets of these cytokines. For example, LPS has been shown to induce expression of IL-1, IL-6, TNF, IL-1 receptor antagonist, GM-CSF, and G-CSF.[349] In contrast, IL-3 and GM-CSF failed to induce the expression of either GM-CSF or G-CSF but were found to induce M-CSF expression. M-CSF has been shown to induce peritoneal macrophages to activate expression of GM-CSF and IL-6 at the transcriptional level, but additional signals are necessary to induce the release of the functional cytokine proteins from the cells.[356] Murine bone marrow–derived macrophages have been reported to constitutively express the messenger RNA (mRNA) for M-CSF and SCF, and the level of expression can be enhanced by treating the cultures with pokeweed mitogen.[357]

The different HGF genes in monocytes can be upregulated by a variety of different mechanisms. In the case of IL-6, LPS and *Mycobacterium tuberculosis* activate gene expression at the transcriptional level through activation of the transcription factors NF–IL-6 and NF-κB.[358] In contrast, activation of IL-1 and IL-6 expression by *Salmonella typhimurium* porins is largely mediated by mRNA stabilization.[359] Cytokine activation of monocyte IL-6 expression also occurs by various mechanisms, often involving interactions between NF-κB and NF–IL-6.[360] IL-2, IL-3, and GM-CSF have all been shown to induce monocyte expression of IL-6, and this expression is inhibited posttranscriptionally by treatment with IL-4.[349,352] In the case of G-CSF, expression can be activated by treatment of monocytes with either IL-1 or LPS (IFN-γ potentiates the LPS response[361]); IL-4 given simultaneously can block this induction, an effect that is not mediated by mRNA stability but rather is mediated at the transcriptional level.[362] These interactions between monocytes and T cells and the cytokines they produce, although complicated, are clearly important in determining the direction and extent of the resulting immune responses and are likely to play a key role in controlling the cytokine network.

Dendritic cells, which have been characterized as potent antigen-presenting cells, are also an important source of HGFs and other cytokines.[363] With the availability of cytokines such as FLT3L, GM-CSF, IL-3, and IL-4, it has become much easier to generate dendritic cells from both myeloid and lymphoid sources in significant numbers for further studies.[218,364] Originally believed to be largely of myeloid cell origin, it is now recognized that some are likely derived from myeloid cells and others have their origins in the lymphoid lineages.[365] Interestingly, different types of dendritic cells, matured under different conditions, can serve to polarize cytokine production by maturing T-helper cells[366] and therefore are likely to play key roles in determining the outcomes of immune responses.

Different populations of fibroblasts, endothelial cells, and epithelial cells can be stimulated to produce cytokines by treatment with LPS,[367] phorbol esters,[331] or other cytokines, including IL-1,[182] TNF,[368] and platelet-derived growth factor (PDGF).[369] In many tissues, this is likely to be an integral part of the host response to infection: Cytokine production at the site of infection should result in local activation of host defense effector cells and the systemic recruitment of more effector cells until the infection is cleared.[370] In bone marrow, thymus, and spleen, these cell populations are likely to be critical components of the local microenvironment, which is involved in the normal proliferation, development, and differentiation of cells of the hematopoietic and lymphopoietic systems. The control of production of the various HGFs in the steady state is still poorly understood.[370]

Fibroblasts and endothelial cells are important sources of many of the HGFs, including G-CSF,[169] M-CSF,[151] GM-CSF,[331] IL-6,[371] IL-11,[299] SCF,[152] and FLT3L.[228,247] This expression is regulated both transcriptionally and posttranscriptionally by exposure to LPS, phorbol esters, or cytokines such as IL-1, TNF, and IFN-γ.[169,372,373] SCF expression has been reported to be constitutive in human stromal bone marrow cultures, in endothelial cells and in bone marrow– derived fibroblasts, and is not responsive to IL-1.[374]

Although it is not clear that stromal fibroblasts from bone marrow are any more or less capable of cytokine production than fibroblasts from other tissues, because of their proximity to stem and progenitor cells they have long been studied for their ability to express HGFs. Many of these cells constitutively express the tyrosine kinase receptor ligands M-CSF and SCF.[374,375]

Following myeloablation, circulating levels of many HGFs increase dramatically. In some cases this might result from mechanisms that sense low levels of the various blood cells. However, Hachiya and colleagues[376] have found that in culture, TNF and IL-1 synergize with irradiation to upregulate the expression of GM-CSF both through mRNA stabilization and activation of gene transcription. These observations raise the possibility that the myeloablative agents themselves may directly induce or enhance HGF production in vivo following various cancer therapy regimens.

Endothelial cells are another important source of HGFs. Human endothelial cells produce G-CSF, GM-CSF, and M-CSF in response to inflammatory cytokines such as IL-1 and TNF.[377,378] In contrast to G-CSF and GM-CSF, SCF mRNA is expressed constitutively by human umbilical vein endothelial cells (HUVECs).[379] The levels of SCF mRNA are further increased in response to inflammatory mediators, including IL-1 and LPS. This induction results predominantly from mRNA stabilization by approximately threefold. Increased expression of GM-CSF mRNA in HUVECs is also at least in part mediated by mRNA stabilization.[380] Possibly the induction of SCF mRNA in endothelial cells contributes to the elevated plasma levels of this factor in patients with sepsis or inflammatory diseases.[379]

Regulation of EPO Expression by Hypoxia

Erythropoietin has long been recognized as the physiologic regulator of red cell production.[381-383] It is produced in the kidney and in the fetal liver in response to hypoxia or exposure to cobalt (II) chloride; the mechanism of the

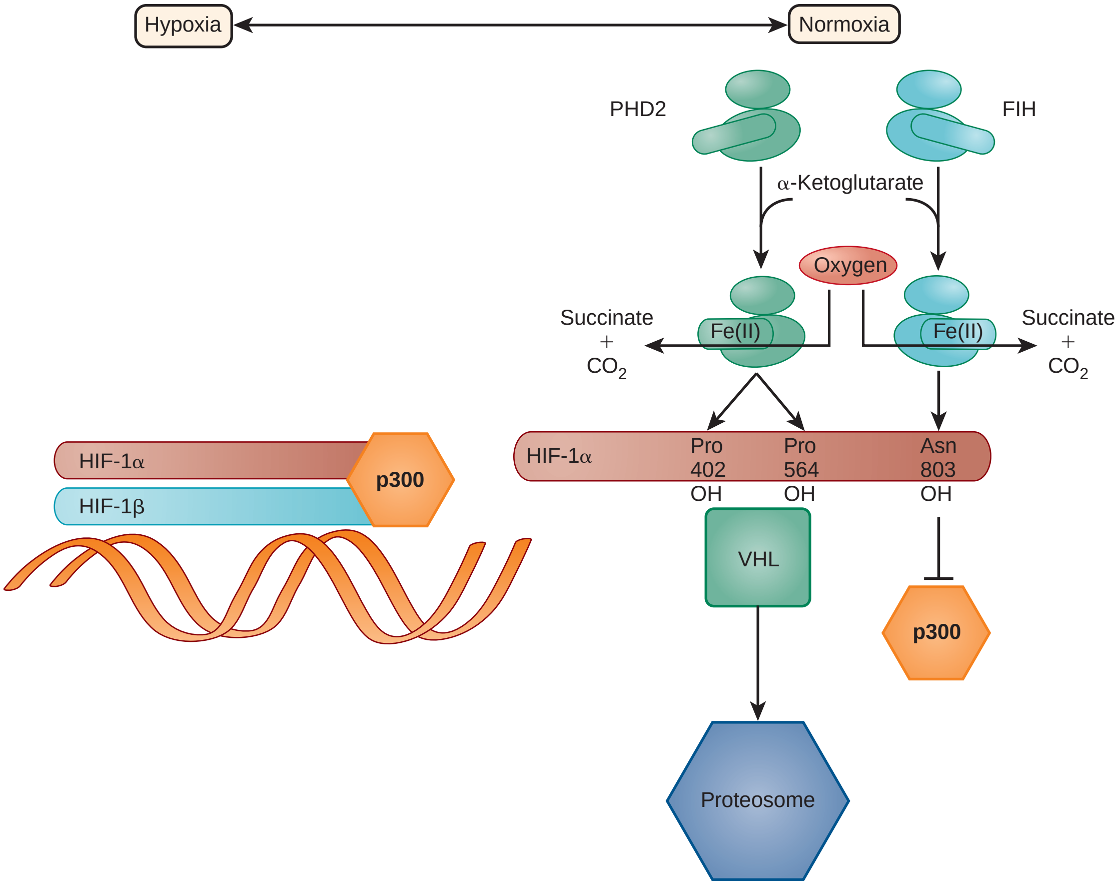


Figure 1-14 Hypoxia-inducible regulation of Epo production. Under normoxic conditions hypoxia-inducible factor 1α *(HIF-1α)* undergoes prolyl hydroxylation at Pro402 and Pro564 that leads to binding of HIF-1α to the von Hippel–Lindau *(VHL)* protein and subsequent ubiquitin-mediated destruction. This dioxygenase enzymatic reaction is catalyzed by a prolyl hydroxylase termed prolyl hydroxylase domain 2 *(PHD2)*. A second hydroxylation at asparagine 803 prevents binding of HIF-1α to its transcriptional coactivator p300, and is catalyzed by a hypoxia-inducible factor asparaginyl hydroxylase called *factor-inhibiting hypoxia-inducible factor (FIH)*. Both these reactions are dependent on oxygen, Fe(II), and α-ketoglutarate, which is oxidized to succinate with the release of CO_2. Under hypoxic conditions both hydroxylases are inhibited, leading to an increase in HIF-1α and recruitment of the p300 coactivator, which together with the ubiquitously expressed HIF-1β, activates transcription.

switch of production from predominantly fetal liver to predominantly kidney in adults is largely unknown.[384] Beck[385] and Semenza[386] showed that the *Epo* gene contains a hypoxia response element in the 3′ flanking sequence.

Nuclear factors present in hypoxic but not normoxic cells were identified as a heterodimeric basic helix-loop-helix transcription factor complex designated hypoxia-inducible factor–1 (HIF-1), comprising inducible HIF-1α and constitutively expressed HIF-1β.[8,9,387] HIF-1 is induced in a variety of cell types in response to hypoxia or cobalt, indicating that while it is important in the activation of EPO expression, it is also important in the activation of many other hypoxia-inducible genes.[8,388] HIF-1 has been shown to bind to an enhancer sequence located approximately 130 bp downstream from the poly-A addition signal of the *Epo* gene. This enhancer segment has been shown to render other promoter-reporter gene constructs responsive to hypoxia, with typical inductions in the range of 4-fold to 15-fold, significantly less than the 50-fold to 100-fold induction observed with the chromosomal *Epo* gene in Hep3B cells.[386] In addition to HIF-1 and its role on the 3′ *Epo* gene enhancer, other studies have identified a 53-bp sequence from the *Epo* promoter that confers oxygen sensitivity (sixfold to tenfold inducibility) to a luciferase reporter gene.[389] Combining the enhancer and promoter sequences results in cooperative (fiftyfold) inducibility of transcription in response to hypoxia, approaching that observed in vivo.

HIF-1α protein levels are regulated by binding to the von Hippel–Lindau (VHL) tumor suppressor followed by ubiquitin-mediated proteosomal degradation (Fig. 1-14).[390,391] Under normoxic conditions, a prolyl hydroxylase uses molecular O_2, iron (Fe II), and α-ketoglutarate to hydroxylate Pro402 and Pro564 in human HIF-1α, which leads to VHL binding and proteosome-mediated proteolysis. A second hydroxylation of Asn 803 by an asparaginyl hydroxylase (similarly dependent on O_2, Fe II, and α-ketoglutarate) blocks the C-terminal interaction of HIF-1α with the transcriptional coactivators p300/CBP.[10] Under hypoxic conditions both hydroxylases are inhibited, leading to escape from ubiquitin-mediated proteolysis and an increase in HIF-1α protein, as well as recruitment of the p300/CBP and transcriptional activation.[392-395]

Regulation of Thrombopoietin Gene Expression

The cloning and expression of the gene for thrombopoietin[396] has provided new insight into the regulation of levels of platelets.[153] Gene disruption studies of *Mpl*, the receptor for TPO in mice, have shown that in the absence of the function of this pathway, mice have only 15% of the normal levels of circulating platelets.[322] Thus while redundancy among the growth factors, perhaps including SCF, IL-3, IL-6, and IL-11, can partially compensate for dysfunctional Mpl signaling, TPO, like EPO in the erythrocyte lineage, appears to be the major regulator of circulating platelet levels.[197] However, in contrast to the control of EPO production, *Tpo* gene expression does not seem to be transcriptionally regulated or significantly influenced by platelet levels.[397] It may be regulated by the megakaryocyte/platelet mass.[398] In adult mice, the major sources of Tpo mRNA are the liver and kidney; in both organs, the gene is constitutively expressed and is not significantly upregulated during thrombocytopenia. However, circulating levels of TPO increase rapidly during thrombocytopenia and decline as platelet counts return to normal.[399,400] The observation that platelets themselves can remove TPO from thrombocytopenic plasma in vitro has led to the model that TPO is constantly produced and released into circulation but, in normal circumstances, is rapidly removed by the circulating platelets and possibly megakaryocytes as well.[398-400] During thrombocytopenia, the platelet shortage fails to remove TPO as fast as it is made, resulting in elevated levels and stimulation of platelet production. This mechanism is similar to one proposed some years ago by Stanley and associates[401] for the regulation of circulating M-CSF levels directly through consumption by the monocytes themselves.

HEMATOPOIETIC GROWTH FACTOR RECEPTORS

Types of Hematopoietic Growth Factor Receptors

Analysis of the actions of the HGFs on purified murine or human stem and progenitor cells (see below) has shown that there is considerable overlap in the action of the HGFs. Some insight into the apparent overlap in biologic activities of many cytokines has come from analysis of their structural homologies and from the cloning of many of their receptors. These receptors are all type 1 membrane glycoproteins with extracellular N-termini and single transmembrane domains, and they fall into two major classes. Receptors (Rs) such as KIT, FMS (the M-CSFR), and FLT3 are characterized by a cytoplasmic tyrosine kinase domain (RTKs), whereas most of the other receptors lack cytoplasmic tyrosine kinase activity and can be divided into four subclasses (Table 1-3). Most of the HGFRs (class 1) fall into a superfamily with structural features based on two linked fibronectin (FBN) type III domains (Fig. 1-15). Analogous FBN domains are found in the IFN (class 2) receptors, and the class 1 and 2 structures probably evolved from a common primitive adhesion molecule.[402] Although the TNF family of receptors (class 3) are characterized by an extracellular fourfold repeat of approximately 40 amino acids that contains 6 conserved cysteine residues (Cys repeat),[149] the IL-1Rs (class 4) feature extracellular immunoglobulin-like repeats. Although the discussion below is focused mainly on the HGFRs, the RTKs activate many of the same signaling cascades.[403,404]

TABLE 1-3 Hematopoietic Growth Factor Receptor Classes

Type	Receptor	Cytokine
Tyrosine Kinase (Ig repeats)	KIT, M-CSFR (FMS)	Four-α-helix bundle
Non–Tyrosine Kinase		
Class 1: HGFRs (FBN III domains)		Four-α-helix bundle
Shared βc	IL-3R, GM-CSFR, IL-5R	
Shared gp130	IL-6R, LIFR, IL-11R, IL-12R, OSMR	
Shared γc	IL-2R, IL-4R, IL-7R, IL-9R, IL-15R	
Single chain	G-CSFR, EpoR, TpoR (MPL)	
Class 2 (FBN III domains)	IFNα/βR, IFNγR	
Class 3 (Cys repeats)	TNFR I, TNFR II, FAS, CD40	β-jellyroll wedge
Class 4 (Ig repeats)	IL-1R I and II	β-trefoil fold

Structure and Binding Properties of Receptors

Prototypes for the class 1 structure are the (nonhematopoietic) prolactin and growth hormone receptors.[405-407] These polypeptides share a number of features (Fig. 1-16). The major homology lies in the extracellular domain, which is characterized by four conserved cysteine residues in the N-terminal FBN III repeat and a Trp-Ser-X-Trp-Ser (WSXWS) motif in the linked C-terminal FBN III repeat that forms a hydrophobic hinge between the two domains. In addition, the IL-6 family of receptors has members that each have an N-terminal immunoglobulin-like domain as well as extra FBN III repeats. The cytoplasmic regions of the receptor family show much less homology, although membrane proximal domains rich in prolines (box 1, within 20 amino acids of the membrane) and acidic residues (box 2), separated by a positionally conserved tryptophan, have been defined. Mutations within the box1/2 domains inactivate the mitogenic function of the receptors that have been examined,[408] and mutations of the conserved tryptophan inactivate some receptors but not others.[409] An additional interesting feature of many of the HGFRs is that receptor subunits are shared. GM-CSF, IL-3, and IL-5 all have receptors with unique alpha chains that bind their respective ligands with low affinity. They share a common beta chain (βc) that converts ligand binding from low to high affinity in each case and is thought to be critical for signal transduction.[410] A similar arrangement is evident with the IL-6, LIF, OSM, IL-11, and CNTF receptors, all of which share a common beta chain, namely gp130. The finding

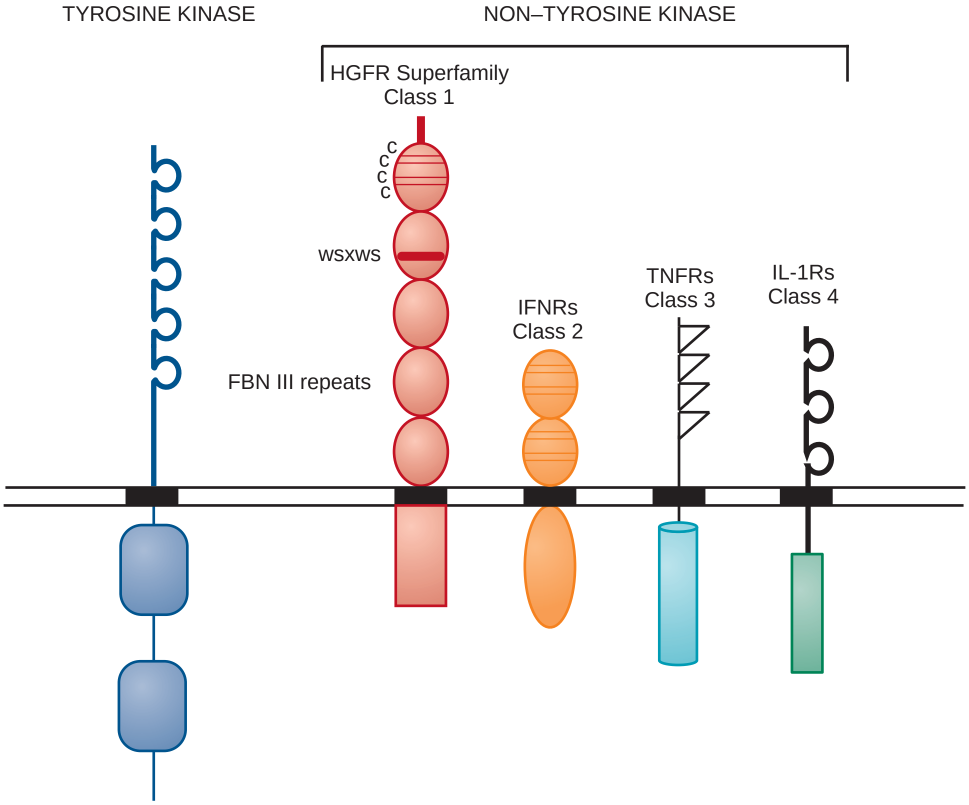

Figure 1-15 Receptors such as KIT, FMS (the macrophage colony-stimulating factor receptor), and FLT are characterized by a cytoplasmic tyrosine kinase domain, whereas most of the other receptors lack cytoplasmic tyrosine kinase activity and can be divided into four subclasses. Most of the hematopoietic growth factor receptors *(HGFRs)* (class 1) fall into a superfamily with structural features based on two linked fibronectin *(FBN)* type III domains; analogous FBN domains are found in the interferon receptors *(IFNRs)* (class 2); the tumor necrosis factor family of receptors *(TNFRs)* (class 3) are characterized by an extracellular fourfold repeat of approximately 40 amino acids that contains 6 conserved cysteine residues (Cys repeat); and the interleukin-1 receptors *(IL-1Rs)* (class 4) feature extracellular immunoglobulin-like repeats.

of shared subunits explains to a certain extent why the actions of GM-CSF and IL-3 overlap on many cells, and why IL-6, LIF, and IL-11 all share pleiotropic actions on HSCs and hepatic cells. The gamma chain of IL-2R is now known to be shared by the IL-4,[411,412] IL-7,[413] IL-9,[414] IL-15,[415] and IL-21[416] receptors. Other members of the HGFR superfamily that act on lineage-restricted cells, such as EPOR, G-CSFR, and thrombopoietin (TPO)R, appear not to require an additional subunit for ligand binding or signal transduction.

The number of IL-3, GM-CSF, G-CSF, and EPO receptors per cell is strikingly low (≈1000 sites per cell), whereas those for M-CSF are about one log higher. In all cases affinity of a receptor for its ligand is high, with dissociation constants usually in the picomolar range. Stimulation of target cells can occur at concentrations of factor that are orders of magnitude lower than the equilibrium constant at which 50% of receptors are occupied, and therefore it is apparent that low receptor occupancy is sufficient to produce biologic effects.

Receptor Function

Lineage-Specific Factors and Induction of Differentiation

Do lineage-specific receptors direct differentiation, or do intracellular proteins specific for lineage-restricted cells have that function? With respect to receptor-driven events, a proximal cytoplasmic domain of the G-CSFR is essential for proliferation, whereas a more distal domain is important for induction of acute-phase plasma protein expression when the receptor is transfected into hepatoma cell lines,[417] or granulocyte-specific proteins when it is introduced into murine IL-3–dependent factor-dependent cell (FDC-P1) cells.[418] Support for a role for the G-CSFR in granulocyte differentiation comes from sequence analysis of the receptor in two patients with severe congenital neutropenia (Kostmann disease) who went on to develop AML.[419] Two different point mutations in the G-CSFR gene resulted in truncations of the C-terminal cytoplasmic region of the receptor and coexpression of both mutant and wild-type genes. The mutation was present in the neutropenic phase in one of the patients, suggesting that the mutation was not acquired along with the leukemia. Functional analysis by transfection of mutant or wild-type genes into murine 32D.C10 cells showed that the mutation acted as a “dominant negative” and prevented differentiation in response to G-CSF. Other evidence for an inductive role of receptors comes from murine long-term bone marrow cultures infected with a retroviral *Fms* vector that yielded a pre–B line with an immunoglobulin heavy-chain gene rearrangement. This line grew in IL-7 or M-CSF;

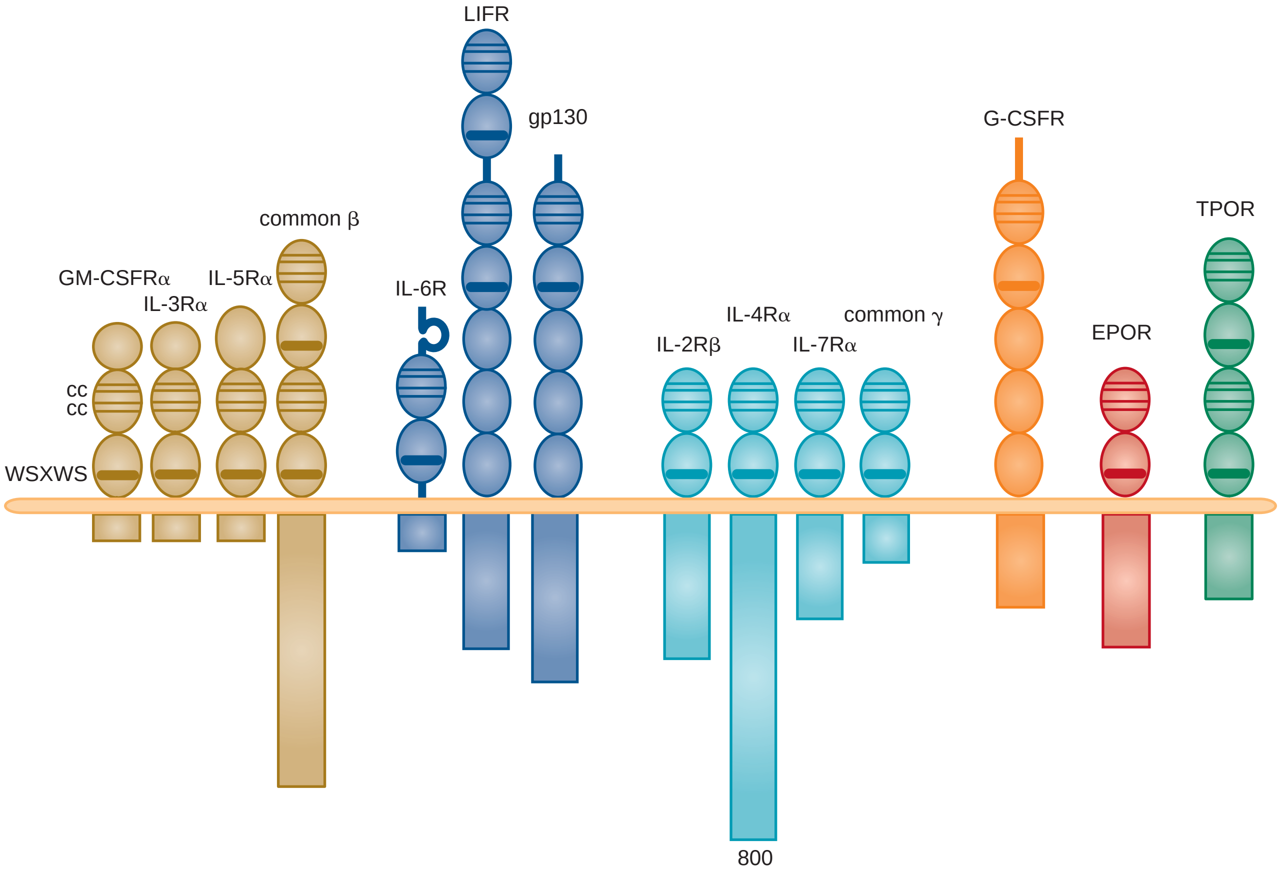

Figure 1-16 Hematopoietic growth factor receptor family. Diagram of some of the hematopoietic growth factor receptors that have been cloned. The extracellular domains are all characterized by one or two regions that contain four conserved cysteines and a tryptophan-serine-x-tryptophan-serine *(WSXWS)* motif, like the prolactin receptor. Unique features: IL-6 contains an immunoglobulin-like domain *(open circle)*; and G-CSF contains a fibronectin type III–like region *(cross-hatching)*. The intracellular domains show less homology. An additional interesting feature of many of the hematopoietic growth factor receptors is that receptor subunits are shared (in particular, the IL-3R, IL-6R, and IL-2R groups. In contrast, lineage-restricted receptors such as the EPOR, G-CSFR, and thrombopoietin (Tpo)R appear not to require an additional subunit for ligand binding or signal transduction.

interestingly, the switch to M-CSF led to macrophage maturation, suggesting that signals from this receptor can determine differentiation in these bipotent cells.[420] Last, transduction and stable expression of the EPOR in IL-3–dependent Ba/F3 cells results in cells that produce globin mRNA upon EPO stimulation but not IL-3 stimulation[421]; and a chimeric receptor that comprises the extracellular domain of GM-Rα and the cytoplasmic domain of the EPOR can induce increased glycophorin A expression in Ba/F3 cells, in contrast to the GM-Rα/βc control.[422] Although these experiments suggest that elements of the cytoplasmic domains of these receptors can direct both proliferation and differentiation, experiments with cell lines must be interpreted with caution. Definitive proof that the EPOR is not specifically required for erythroid differentiation comes from retroviral expression of the prolactin receptor in wild-type and *Epor*$^{-/-}$ progenitors; these cells differentiate efficiently in prolactin, indicating that there is no unique instructive role for the EPO in erythropoiesis.[423] However, the prolactin receptor activates similar signaling pathways to the EPOR such as STAT5, and therefore could perhaps readily substitute for EPOR function. In contrast, GM-CSF cannot rescue lymphopoiesis in GM-CSFR transgenic mice crossed with IL-7–deficient animals; furthermore, common lymphoid progenitors that express ectopic GM-CSFR differentiate into myelomonocytic cells, indicating plasticity in common lymphoid progenitors and an instructive role for GM-CSFR in this context.[424]

Taken together, it is reasonable to conclude that the major role of HGFRs is the survival, the amplification, and, particularly in the case of the lineage-specific receptors, the completion of an intrinsic differentiation program of committed progenitor cells. There is, however, overlap of expression, as with EPOR expression on megakaryocyte progenitors.[113]

Signal Transduction

Hematopoietic Growth Factor–Induced Tyrosine Phosphorylation. Several signaling proteins and pathways are common to many different receptor types. A paradigm common to receptors both with and without endogenous tyrosine kinase activity is that ligand binding induces homodimerization or heterodimerization of receptor subunits, and this is followed rapidly by transient tyrosine phosphorylation of the cytoplasmic domain of the

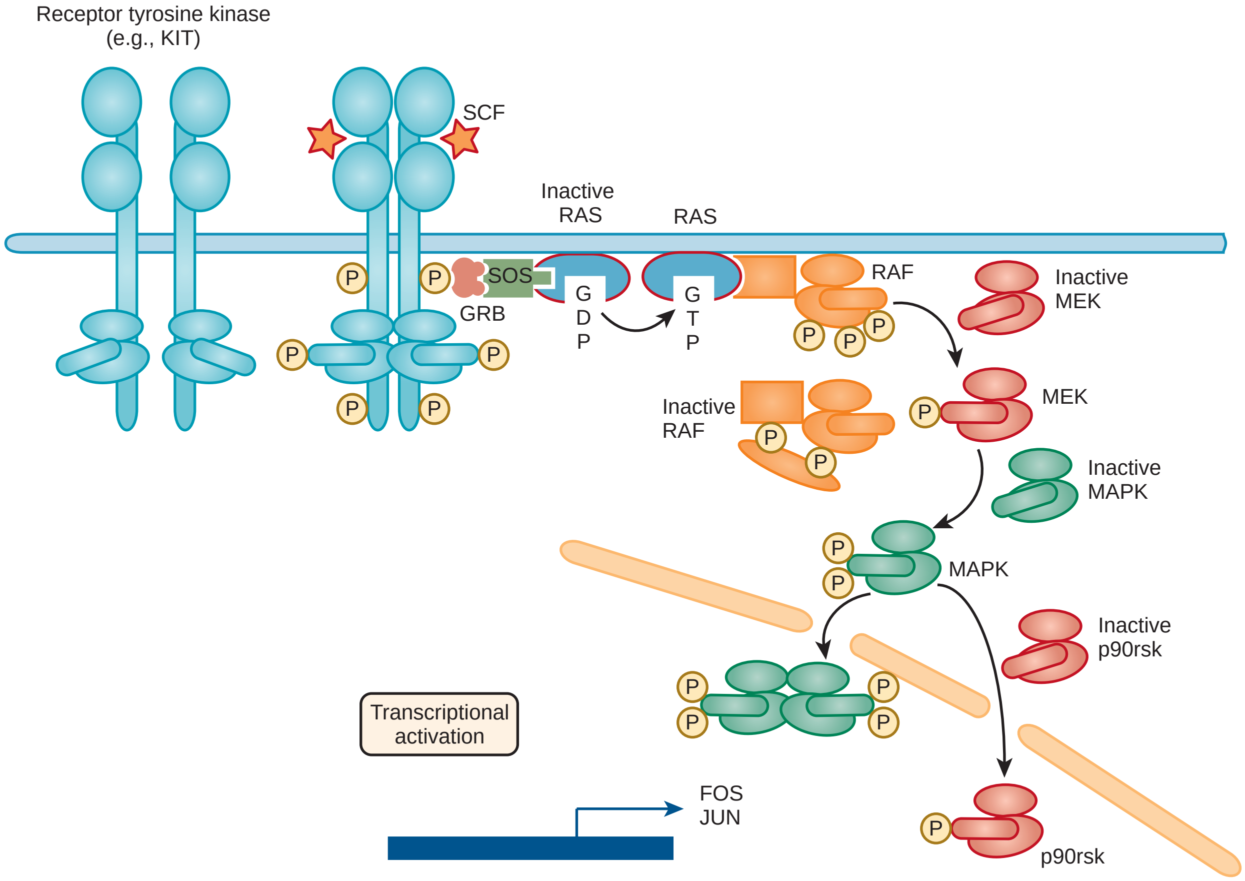

Figure 1-17 Signal transduction through a receptor tyrosine kinase such as KIT. The figure illustrates that the cytosolic domains contain a protein tyrosine kinase catalytic site that forms a functional dimer after ligand binding. The kinases phosphorylate each other, which causes the activation lip to move out of the catalytic site, allowing the binding of adenosine triphosphate or a protein substrate. The kinase phosphorylates other tyrosines in the receptor cytosolic domain that function as docking sites for other signaling proteins. One of the major pathways is RAS activation and phosphorylation of c-raf, MEK (MAPKK), MAPK, and p90S6k (or p90RSK) and induction of FOS/JUN and probably bcl-2, important for cell proliferation and survival.

receptor itself, of cytoplasmic tyrosine kinases, and of other cytoplasmic proteins involved in generating different signaling cascades (Fig. 1-17). In the case of the receptors with intrinsic tyrosine kinases, ligand-induced activation of their catalytic function leads to transphosphorylation or autophosphorylation of dimerized receptor subunits and activation of three major signaling cascades: RAS/MAP kinase; phosphoinositol (PI)-3′ kinase/protein kinase B (PKB, also known as *AKT*); and phospholipase C (PLC)/inositol trisphosphate (IP_3)/diacylglycerol (DAG)/protein kinase C (PKC). Receptors that lack a tyrosine kinase domain must recruit cytoplasmic tyrosine kinases. For the class 1 cytokine receptors the family of Janus kinases (JAKs) fulfills this role, but other nonreceptor kinases have been identified and may also be important. Tyrosine phosphorylation within the receptor cytoplasmic domain creates docking sites for substrates characterized by the presence of *src* homology 2 (SH2) domains. These SH2 domains recognize phosphotyrosine in the context of specific short sequences of amino acids.[425] This leads to activation of the three signaling cascades mentioned above (RAS, PI -3′ kinase, and PLC) as well as the activation by JAK of a critical family of *s*ignal *t*ransducers and *a*ctivators of *t*ranscription, the STAT proteins.

There are four known members of the JAK family, JAK1, JAK2, JAK3, and TYK2.[426-428] All are 130- to 134-kD related proteins that have an amino-terminal receptor-binding domain, a carboxy-terminal kinase domain, and a middle domain that regulates kinase activity (Fig. 1-18). Although it first appeared that HGFs activated JAK proteins in a rather promiscuous manner, some patterns have emerged (Table 1-4). Thus receptors that are comprised of dimers such as the EPOR, G-CSFR, and TPOR associate with JAK2 (or to a lesser extent JAK1) in either a constitutive or ligand-dependent manner. Ligand binding and consequent clustering of receptor molecules leads to JAK2 aggregation and transphosphorylation at the lysine–glutamic acid–tyrosine–tyrosine (KEYY) site in the kinase activation loop. For example, the inactive EPOR exists as a homodimer each cytoplasmic domain of which is irreversibly bound to a molecule of JAK2. EPO binding to the extracellular domain of the receptor induces a conformational change that brings the JAK kinase domains together, resulting in rapid tyrosine transphosphorylation.[429] In vitro experiments show that

Figure 1-18 Signal transduction through a cytokine receptor such as the EPOR: JAK2 is tightly bound to the receptor. The JAKs contain a C-terminal tyrosine kinase domain and an N-terminal receptor-binding domain separated by a regulatory domain. The homodimeric receptor undergoes a conformational change after ligand binding that brings together associated JAK2 molecules, which then phosphorylate each other on a tyrosine in the activation lip, leading to tyrosine phosphorylation of the receptor. These tyrosines act as docking sites for STAT5 and other signal transduction proteins containing *src* homology 2 *(SH2)* and phosphotyrosine-binding (PTB) domains. The STAT proteins contain an SH2 domain that contains the completely conserved GTFLLRFSS sequence; mutation of the arginine residue eliminates function. The SH2 domain is critical for recruitment to the receptor and for STAT dimerization. The N-terminal DNA-binding domain is highly conserved, and after STAT dimerization binds similar symmetric dyad sequences (e.g., STAT5: TTCC[A→T]GGAA). DNA binding is totally dependent on phosphorylation of a critical tyrosine at the C-terminus. *PI3K,* Phosphatidylinositol 3′-kinase; *PI3,4bisP,* phosphatidylinositol 3,4-bisphosphate; *PI3,4,5trisP,* phosphatidylinositol 3,4,5-trisphosphate; *PIP,* phosphatidylinositol 4-phosphate; *PKB,* protein kinase B; *UTR,* untranslated region. *(For an excellent review see Cell signaling II: signaling pathways that control gene activity. *Nonreceptor tyrosine kinases that associate with receptors are indicated in bold, and references are in superscript.

JAK2 phosphorylation leads to activation of its kinase function, which, taken together with evidence of association of JAK2 with the EPOR, suggests that JAK2 may act as the "master" protein tyrosine kinase that mediates the biologic response to EPO. Support comes from observations that a kinase-negative JAK2 acts as a dominant-negative suppressor of the proliferative response to EPO,[430] and that the box1/box2 proximal cytoplasmic domain of the EPOR is the region that both binds JAK2 and is essential for receptor function.[429] Furthermore, an acquired JAK2V617F mutation, found in almost all patients with polycythemia vera and about half of those with essential thrombocytosis and myelofibrosis, confers constitutive tyrosine kinase activity upon JAK2; it transforms hematopoietic cells when it is coexpressed with homodimeric cytokine type 1 receptors, and is sufficient for the development of polycythemia vera in murine recipients of transplanted JAK2V617F stem cells.[431] A number of other substrates are phosphorylated in response to EPO,[432-434] including nonreceptor kinases such as the p85 subunit of PI-3 K, substrates such as PLC-γ1 and the adaptor molecule Shc, and the tyrosine phosphatases hematopoietic cell phosphatase (HCP or PTP-1C) and Syp (also known as *PTP-1D* or *SH-PTP2*) that down-regulate signal transduction; other kinases such as FES[435] and Vav are also activated.

The other heterodimeric receptors appear to associate with and activate several JAKs (see Table 1-4).[426] The beta common component of the IL-3/GM-CSF receptor is tyrosine phosphorylated after IL-3 or GM-CSF stimulation.[436,437] The tyrosine kinase that is responsible for ligand-induced receptor phosphorylation could be JAK2[438] or JAK1,[439] but the role of other recruited nonreceptor kinases such as LYN,[440] FYN,[441] and FES[442] has not been clearly defined. Truncation mutants of βc show that the proximal cytoplasmic domain (amino acids 449 to 517) can induce JAK2 tyrosine phosphorylation and kinase activation,[443] and this truncated receptor also retains the capacity to induce myc and pim-1 and to induce proliferation in serum-replete conditions but not serum-free conditions.[436,444-446] Both gp130 and leukemia inhibitory factor receptor (LIFR) can associate with and activate JAK1, JAK2, and TYK2, but the pattern of such JAK family activation is distinct in different cell types.[447]

Hematopoietic Growth Factor–Induced Activation of STAT Proteins. The paradigm of the response to IFN has provided another major insight into a subsequent step in JAK family signal transduction. The kinase activities of TYK2 and JAK1 that are activated after IFN-α binding lead to phosphorylation of STAT1α/STAT1β, and STAT2. STAT proteins are characterized by an amino-terminal DNA-binding domain, a conserved SH2 domain, and a critical tyrosine at the carboxyl-terminus. Tyrosine phosphorylated STAT1α/β and STAT2 form heterodimers through their SH2 domains, bind to a 48-kD protein, translocate to the nucleus, and activate gene expression by binding to an interferon-stimulated response element (ISRE).[448-450] STAT1α is also tyrosine phosphorylated (at Y^{701}) after IFN-γ binds to the IFN-γR, and this event is associated with tyrosine phosphorylation of JAK1 and JAK2.[451,452] STAT1α homodimerizes, translocates to the nucleus, and binds to the IFN-γ activated sequence (GAS), thereby transcriptionally activating genes that contain this sequence in their promoters.

The JAK proteins activated by HGFRs also lead to phosphorylation and DNA binding of STAT proteins; four additional members of the STAT family have been cloned: STAT3, STAT4, STAT5, and STAT6 (see Table 1-4). Thus ligand-induced activation of gp130, the signal-transducing component of the IL-6, LIF, IL-11, OSM, and CNTF family of receptors, leads to tyrosine phosphorylation of the JAK-Tyk family and activation of STAT3.[447,453,454] STAT4 expression is restricted to spermatogonia as well as thymic and myeloid cells. STAT4 mRNA levels appear to decline when 32Dcl1 cells differentiate in either G-CSF or EPO.[455] An ovine DNA-binding activity induced by prolactin called *mammary gland factor* was cloned and is named STAT5.[456] STAT5 is activated by EPO and growth hormone[457] as well as IL-3, GM-CSF, and IL-5.[458] This 92-kD protein exists as two highly related proteins, STAT5A and STAT5B (96% identical), which are encoded by different genes. STAT6 is most closely related to STAT5 and is induced by IL-4.[459]

Hematopoietic Growth Factor Signaling Through the RAS Pathway. RAS is a "turnstile" through which signals from many receptors are routed.[460] RAS guanosine triphosphate (GTP) associates with and activates RAF-1 and mitogen-activated protein kinase (MAPK).[461] RAS is a 21-kD membrane-associated protein that cycles between the active GTP-bound forms and the inactive guanosine diphosphate (GDP)-bound forms in response to extracellular signals from various HGFRs, including KIT, IL-3, and GM-CSF receptors, T-cell receptor, IL-2R, and EPO R.[462-465] Activation of RAS is mediated by guanine-nucleotide–releasing factors (GRFs) that catalyze the release of bound GDP and its exchange for GTP, while deactivation occurs by GTPase-activating proteins (GAPs) such as $p120^{GAP}$ and neurofibromin that accelerate the intrinsic activity of RAS, leading to hydrolysis of GTP to GDP. The mammalian prototype for GRF-mediated RAS activation is the epidermal growth factor receptor (EGFR) the cytoplasmic domain of which bears intrinsic tyrosine kinase activity. After ligand-mediated dimerization, the EGFR is activated through autophosphorylation or transphosphorylation of tyrosine 1068. An adaptor protein, Grb2, binds to this phosphotyrosine through its SH2 domain. This in turn leads to the formation of a ternary complex of EGFR, Grb2, and a GRF called *SOS,* which is analogous to the *Drosophila* son of sevenless (SOS) protein.[466] SOS contains a proline-rich region that recognizes two SH3 domains of Grb2, and the complex then activates membrane-bound RAS GDP to RAS GTP (Fig. 1-17). The protooncogene vav also has RAS GDP/GTP nucleotide exchange activity[467] and is activated through tyrosine phosphorylation after cross-linking of the T-cell antigen receptor–CD3 complex. With respect to the HGFRs, IL-2–mediated activation of the IL-2R leads to IL-2Rβ–chain tyrosine phosphorylation and association of the receptor with Shc, another adaptor protein that is characterized by both an SH2 domain and a second phosphotyrosine-binding (PTB) domain.[468,469] Shc itself becomes phosphorylated on tyrosine, and this in turn leads to recruitment of Grb2 and SOS.[470] The IL-3/GM-CSF–mediated signaling cascade involves phosphorylation of the beta subunit itself as well as Shc, with subsequent increased levels of RAS GTP and activation of RAF-1, MEK (also called *MAPK kinase*), and MAPK, followed by induction of FOS and JUN (see Fig. 1-17). This activity was mapped to the cytoplasmic domain of βc between amino acids 626 and 763, whereas a more proximal domain (amino acids 449 to 517) retains the capacity to induce myc and pim-1.[445] The PTB domain of Shc binds to tyrosine 577 of βc after JAK2-mediated phosphorylation of βc.[471] RAS activation is important for both the proliferative and survival (prevention of apoptosis) functions.[446,472] In the case of the EPOR, ligand-induced phosphorylation of Shc and the association of Shc with the EPOR has also been demonstrated; phosphorylated Shc associates with Grb2, and RAS and the MAP kinase pathway is activated.[473-477] In summary, these three examples show that RAS is activated by a number of HGFRs, and that the RAS-RAF-MEK-MAP kinase pathway is important for proliferation and survival of hematopoietic cells.

The RAS pathway may also be important in certain leukemias. Neurofibromin, encoded by the *NF-1* gene, is mutated in patients with autosomal dominant neurofibromatosis type 1 (NF-1). NF-1 shows sequence homology with yeast and mammalian GAP genes. Children with neurofibromatosis have an increased risk of juvenile myelomonocytic leukemia (JMML), monosomy 7 syndrome, and acute myeloblastic leukemia.[478,479] Importantly, leukemic cells from children with NF-1 and myelodysplastic syndrome show loss of the normal NF-1 allele, thus implicating NF-1 as a tumor suppressor gene.[479] NF-1^{GAP} activity is significantly lower in cell lysates prepared from NF-1–associated leukemias than in normal bone marrow or non–NF-1 leukemic lysates.[480] Bone marrow mononuclear cells from patients with JMML show an increase in CFU-GM in response to GM-CSF but not in response to IL-3. Interestingly, fetal liver cells from mice that are rendered null for the *NF-1* gene show similar hypersensitivity to GM-CSF, indicating that NF-1^{GAP} may play a crucial and specific role in the response of myeloid cells to GM-CSF.[480,481] NF-$1^{-/-}$ mice die in utero around day 13.5 to 14.5 from complex cardiac defects, but transplantation of fetal liver cells on day 11.5 to 13.5 into lethally irradiated recipients produces a myeloproliferative syndrome similar to that of the human disease.[481] BCR-ABL is a chimeric oncogenic protein that shows dysregulated tyrosine kinase activity and is implicated in the pathogenesis of Philadelphia chromosome–positive chronic myeloid leukemia. A phosphorylated tyrosine (Y177) in the BCR first exon binds to the SH2 domain of Grb2 and activates RAS.[482] Mutation of the Y177 BCR-ABL to phenylalanine abolishes Grb2 binding and abrogates both BCR-ABL–induced RAS activation and transformation of primary bone marrow cultures.[482] In summary, RAS dysregulation may contribute to the increased proliferation that characterizes these two chronic leukemias.

Phosphatases and Receptor Signaling. The C-terminal domain of the EPOR has a negative regulatory role.[483] It is likely that this effect is mediated by a phosphatase that dephosphorylates kinase-associated tyrosine(s) in this region, as has been shown for the IL-3R.[484] There is a fascinating report of a Finnish family with dominantly inherited benign erythrocytosis.[485] The proband, an Olympic cross-country skier, has a mutation in the EPOR that introduces a premature stop codon and generates a receptor lacking the C-terminal 70 amino acids. This mutation cosegregates with the disease phenotype in this large family. Recent data show that the nontransmembrane protein tyrosine phosphatase SH-PTP1 (also called SHP-1, HCP, and PTP1C) associates via its SH2 domain with tyrosine-phosphorylated EPOR.[486] Mutational analysis mapped the binding site most probably to Y429, and this tyrosine is deleted with the C-terminal truncation of the EPOR in the Finnish family with benign erythrocytosis. Factor-dependent cells that express a Y429,431F mutant EPOR show increased sensitivity to EPO, as do cultured erythroid progenitors from patients with benign erythrocytosis.[486] CFU-E from mice that lack or have impaired SH-PTP1 activity (motheaten or motheaten viable) show a similar increased sensitivity to EPO.[487,488] Therefore, EPO-induced activation and subsequent tyrosine phosphorylation of the EPOR leads to recruitment of SH-PTP1, which then plays a major role in terminating the EPO signal, possibly through dephosphorylation of JAK2[486] or other tyrosine kinases.

Another nonreceptor protein tyrosine phosphatase called SH-PTP2 or SHP2, encoded by the *PTPN11* gene, has 50% to 60% identity with SH-PTP1 in both SH2 and catalytic domains. Despite this similarity, SH-PTP2 appears to be a positive regulator of some growth factor pathways,[489] in particular RAS. Approximately 50% of patients with Noonan syndrome (NS), a developmental disorder characterized by short stature, dysmorphic features, and cardiac defects, have germline mutations in SH-PTP2, and 35% of patients with JMML but not NS have somatic mutations in this gene. Some patients with NS develop JMML, and it appears that the mutations in NS/JMML differ from those found in de novo nonsyndromic JMML,[490] and differ in the degree to which they activate the phosphatase.[491]

Other Inhibitors of Hematopoietic Growth Factor Signaling. Another family of negative regulators is made up of the suppressors of cytokine-signaling (SOCS) proteins. SOCS-1 was discovered by three groups, contains an SH2 domain, and has sequence and structural similarities to an immediate early gene called *CIS* (cytokine-inducible SH2–containing protein).[404,492-494] It is one of an eight-member gene family (SOCS-1 to SOCS-7 and CIS) that is characterized by a central SH2 domain and a C-terminal conserved motif called a *SOCS box*. Unlike the constitutively expressed phosphatases, SOCS expression is induced by many cytokines, including IL-3, EPO, TPO, IL-6, and LIF, and the proteins are expressed in hematopoietic and other tissues.[495] SOCS-1, expressed predominantly in the thymus, interacts directly with the phosphorylated activation loop of (activated) JAKs, and its N-terminus is thought to inhibit adenosine triphophate

(ATP) binding to the activation cleft.[404,492,496] Subsequently, the SOCS box is hypothesized to target the SOCS/signaling complex to the proteosome for degradation by recruiting components of the proteasome machinery, including elongins B and C and Cullin 2.[497,498] SOCS-3 has been shown to inhibit signaling by a different mechanism, which is binding directly to activated receptors and to JAKs without inhibiting JAK activity,[499] whereas CIS can bind to phosphorylated tyrosines on the EPO receptor and thereby inhibit STAT5 signaling.[500]

SOCS knockouts have provided insight into the important physiologic roles of some of these proteins. SOCS-$1^{-/-}$ mice die before weaning with fatty degeneration of the liver, reduced thymic size, lack of T and B cells, and monocytic infiltration of organs.[501,502] This phenotype is similar to mice with elevated IFN-γ, and indeed SOCS-$1^{-/-}$ mice have increased IFN-γ levels; rescue of the animals can be achieved with antibodies to IFN-γ or by crossing mice with IFN-$\gamma^{-/-}$ mice.[503,504] SOCS-$2^{-/-}$ mice are normal at birth but then become significantly larger than wild-type mice, with thickening of the dermis due to excess collagen deposition.[505] Therefore SOCS-2 appears to play an important role in postnatal growth, possibly through the growth hormone/insulin-like growth factor-1 axis. SOCS-$3^{-/-}$ mice are hematopoietically most interesting in that they die at embryonic day 12 to 14 because of massive erythrocytosis.[506] Progenitor cells appear to be hyperresponsive to IL-3 and EPO. Thus SOCS-3 plays a crucial role in inhibiting fetal erythropoiesis. Although mice in which *CIS* has been deleted show no abnormalities, overexpression of CIS induces a phenotype similar to that of *Stat5a*$^{-/-}$ or *Stat5b*$^{-/-}$ animals.[507-510]

BIOLOGY OF HEMATOPOIESIS

Stem Cells

The formed elements of the blood in vertebrates, including humans, continuously undergo replacement to maintain a constant number of red cells, white cells, and platelets. The number of cells of each type is maintained in a very narrow range in the physiologically normal adult, approximately 5,000 granulocytes, 5×10^6 red blood cells, and 150,000 to 300,000 platelets/μL of whole blood (see Appendix for normal values in infancy and childhood). In this section we examine the normal regulatory mechanisms that maintain a balanced production of new blood cells. These regulatory systems are far from completely understood, but present evidence strongly supports the following basic principles, schematically depicted in Figure 1-7:

1. A single pluripotent stem cell is capable of giving rise to many committed progenitor cells. These committed progenitors are destined to form differentiated recognizable precursors of the specific types of blood cells.
2. The pluripotent stem cell is capable of self-renewal. The committed progenitor cells are limited in proliferative potential and are not capable of indefinite self-renewal. In addition to their limited proliferative potential, committed progenitors also "die by differentiation"[511] and their numbers depend on influx from the pluripotent stem cell pool.
3. The proliferative potential and differentiation of stem cells and committed progenitors may be influenced by niche cells or factors derived from them. Thymus-derived lymphocytes appear to contribute to the induction of spleen colony formation in irradiated recipients.[512-515] The hematopoietic role of thymus-derived cells is further supported by experiments demonstrating the defective restorative capacity of bone marrow from congenitally athymic[516] or neonatally thymectomized[517] mice, or rigorously T-depleted human bone marrow.[518]
4. Committed progenitor cells are capable of response to humoral- or marrow stroma–derived regulators, some produced in reaction to the circulating levels of a particular differentiated cell type. In this response, they proliferate and differentiate to form the recognizable blood cells. Under this type of control, amplification of production occurs at the committed progenitor cell level. Most of the regulatory molecules are produced by hematopoietic accessory cells in close proximity to progenitor cells. As differentiation proceeds, sensitivity to the late-acting factor increases. This late-acting regulator may serve to protect the highly proliferative but numerically limited immature progenitor compartment from exhaustion or death by differentiation under these stress conditions.
5. Hematopoietic differentiation requires an appropriate microenvironment. In normal humans, this environment is confined to the bone marrow, whereas in the mouse the microenvironment includes both the spleen and the bone marrow. The existence of the Steel (Sl) strains of mutant mice[519,520] that exhibit a deficiency in the hematopoietic microenvironment (see below) suggests that the interactions between hematopoietic progenitors and the bone marrow microenvironment involve very specific molecular mechanisms.[521] A number of early hematopoietic cells, including the pluripotent stem cells and certain committed progenitor cells, have been demonstrated in the circulation of normal individuals and/or experimental animals.[75,522-524] The capacity of HSCs to negotiate nonhematopoietic tissues via the circulation is especially significant in relation to bone marrow transplantation, which is carried out by infusion of bone marrow or blood cells from the donor into the circulation of the recipient.[525] For example, blockade of hepatic asialoglycoprotein receptors enhances stem cell engraftment in murine spleen and marrow.[526] There is also convincing evidence that murine stem cells (CFU-S) and progenitors (CFU-GM) express "homing" or adhesive lectin receptors that bind to the mannose and/or galactose presented on stromal cells. For example, homing of transplanted mouse progenitors can be blocked by synthetic neoglycoproteins with these specificities, suggesting that stromal cells are likely to express these sugars.[527] SDF-1/chemokine (CXCR4) signaling, adhesion molecules, including VLA-4/VCAM-1 and CD44/hyaluronic acid interactions, are also important in the regulation of homing.[528]

If only 10% to 20% of stem cells are in cycle in the resting state, what is their role with regard to self-renewal versus differentiation, and what is the role of the noncycling stem cells? The hypothesis that a series of stem cells may contribute clones successively to maintain hematopoiesis throughout the life span of an individual was first advanced by Kay.[529] Support for this hypothesis comes from transplant studies of recipients of small numbers of bone marrow cells[530,531] and from experiments in which mixtures of fetal liver cells from different inbred mouse strains were introduced into W-mutant fetuses. W mutants exhibit a genetic deficiency of HSCs (as well as germ and follicle cells) (see below). Long-term monitoring showed clonal dominance followed by a decline of cells of particular genotypes.[531]

The use of retroviral-mediated gene transfer to mark HSCs at first lent support to this hypothesis. Analysis of the viral integration patterns at intervals after transplantation documented concurrent contributions of small numbers of stem cells to hematopoiesis, with changing patterns over time.[532,533] These conclusions are not supported by the work of Harrison,[534] who measured variances at successive intervals in recipients of marrow mixtures from two congenic donors. The high correlations observed in this study suggest that the transplanted stem cells continuously produce descendants. However, if 10 to 20 (or more) clones are contributing to hematopoiesis simultaneously, then even with clonal succession one might expect variances between two alloenzymes to be minimized at sequential samplings. Furthermore, a longer-term analysis of viral integration patterns in multiple-lineage progeny of stem cells transplanted into mice shows that integration patterns are unstable initially but then stabilize and maintain consistency over many months.[535] Although this consistency does not appear to support the clonal succession hypothesis, the contributory role of unmarked stem cells in these experiments cannot be assessed. Furthermore, it is not possible to determine whether the immediate progeny of the transplanted (and retrovirally marked) stem cells might not all still have self-renewal capacity and subsequently contribute to hematopoiesis successively. Such clones would carry the same integration marker. A problem with the transplant approach discussed above is that the preparation required for successful transplantation may perturb hematopoiesis and complicate interpretation of the results. A resolution of the problem came from studies in which a nontoxic dose of bromodeoxyuridine in drinking water was fed to mice.[536,537] Bromodeoxyuridine is incorporated into DNA by proliferating cells, and measurement of incorporation rates into primitive stem cell populations over time can be used as a monitor of proliferative history. Under steady-state conditions, approximately 5% of the LTR-HSCs were in cycle and another 20% in the G_1 phase, with approximately 8% entering the cell cycle per day. By 6 days, 1 month, and 6 months, 50%, 90%, and 99%, respectively, of the stem cell pool had incorporated the label.[537] Because the size of the stem cell pool remains constant, these data indicate that 50% of dividing LTR-HSCs must self-renew; this could be accomplished by asymmetric division or by symmetric division in which half the cells give rise to LTR-HSCs and the other half to differentiating cells. More recently, fluorescent marking studies and bar-coding strategies have suggested that significant numbers of clones participate in hematopoiesis.[538,539]

Transcription Factors and Stem Cells

Although the factors that control the "decisions" of stem cells to undergo either self-renewal or commitment to differentiate down one of the alternate lineage pathways are poorly understood, in recent years nuclear transcription factors have been characterized that play a role in stem or early progenitor cell proliferation and lineage commitment.[540,541] The Tal1, LMO2, and GATA family of transcription factors is important in this regard. In particular, tal-1/SCL, a basic helix-loop-helix (bHLH) transcription factor, is expressed in biphenotypic (lymphoid/myeloid) and T-cell leukemias[542,543] and in both early hematopoietic progenitors and more mature erythroid, mast, megakaryocyte, and endothelial cells.[544,545] Targeted disruption of the *Tal-1/Scl* gene leads to death in utero from absence of blood formation, and lack of in vitro myeloid colony formation suggests a role for this factor very early during hematopoiesis at the pluripotent or myeloid-erythroid stem cell level.[546,547] Another transcription factor implicated in T-cell ALL is the LIM domain–only nuclear protein (Lmo2).[548,549] Mice that lack this factor die in utero and have the same bloodless phenotype as the *Tal1*$^{-/-}$ animals.[550] Interestingly, although Lmo2 does not show sequence-specific DNA binding, immunoprecipitates in erythroid cells show that Lmo2 exists in a complex with Tal1,[551,552] suggesting a physiologic interaction in vivo. GATA2 is expressed in the regions of the *Xenopus* and zebrafish embryos that are fated to become hematopoietic, and is highly expressed in progenitor cells.[545,553-555] Overexpression of GATA2 in chicken erythroid progenitors leads to proliferation at the expense of differentiation.[556] Targeted disruption of the *Gata2* gene by homologous recombination in embryonic stem cells leads to reduced primitive hematopoiesis in the yolk sac and embryonic death by day 10 to 11.[557] Definitive hematopoiesis in liver and bone marrow is profoundly reduced, with loss of virtually all lineages, and in vitro differentiation data show a marked deficiency of SF-responsive definitive erythroid and mast cell colonies and reduced macrophage colonies, suggesting that GATA2 serves as a regulator of genes that control HGF responsiveness or proliferation of stem and/or early progenitor cells. Dominant mutations in *GATA2* have recently been described in the monoMAC syndrome, characterized by nontuberculous mycobacterial infections (frequently *Mycobacterium avium* complex [MAC] infections), fungal infections, disseminated human papillomavirus infection, and pulmonary alveolar proteinosis. Patients have a marked reduction of monocytes, NK cells, and B cells, and can develop myelodysplasia and leukemia.[558,559]

These data contrast with the later time of embryonic death (day 15) from anemia during the midfetal liver stage in mice with targeted disruption of *Myb*[560] and *Rb*[561-563] and severe forms of *W* and *Sl* mutations (see below).[564] Myb has been shown to be absolutely required for normal hematopoietic production during embryogenesis.[565] Embryonic erythropoiesis in *Myb* knockout mice is normal, but there is complete failure of erythropoiesis in fetal liver. Progenitors of other lineages, but not megakaryocytes, were also decreased, indicating that Myb is required for early definitive cellular expansion.[560] Furthermore, a knockdown allele of *Myb* shows that suboptimal levels of Myb favor macrophage and megakaryocyte differentiation whereas higher levels are particularly important for erythropoiesis and lymphopoiesis.[566] An ethylnitrosourea (ENU)-induced allele of *Myb* (M303V) affects the transactivation domain of the protein that interacts with the transcriptional coactivator p300; recessive mice ($Myb^{\mathrm{M303V/M303V}}$) demonstrate increased platelet production, anemia, absence of eosinophils, and defects in B-cell and T-cell lymphopoiesis.[567] These animals were found to have an increase in transplantable HSCs, indicating that Myb has a negative role in HSC self-renewal. Thus Myb appears to have a negative role in HSC and megakaryocyte progenitor proliferation and positive effects on erythropoiesis, eosinophil production, and lymphopoiesis.

Loss of function of the *runx1* (or *AML1*) gene, which encodes the alpha subunit of the heterodimeric core-binding factor (CBF), results in fetal death by day 12.5 because of failure of production of all definitive hematopoietic lineages.[568] CBF recognition sequences are present in the IL-3, GM-CSF, M-CSFR, and T-cell antigen receptor promoters. The *runx1* gene is frequently rearranged in acute myelogenous leukemia (AML) and childhood acute lymphoblastic leukemia (ALL), and is expressed in myeloid and lymphoid cells.[549] Runx1 has been shown to interact with a number of repressors, including GROUCHO domain factors. Runx1 is also a regulator of HSC production in the aorta-gonads-mesonephros region, as well as in adult stem cell homeostasis. A rescue of runx1 by a Tek (Tie2) promoter rescues hematopoiesis during development.

There are GATA1 PU.1 interactions regulating an erythroid/myeloid decision, and there are many other transcription factor interactions, such as CEBPa induction of PU.1 in the myeloid system. Such competition for transcription factors and the regulation of stem cell differentiation appears to be a recurring mechanism in the hematopoietic system. Manipulation of the process actually leads to altered hematopoiesis that can favor a single lineage. This involves a cell fate change rather than a proliferative event.

Homeobox (*HOX*) genes encode transcription factors involved in the establishment of body pattern and tissue identity during development.[569] The human genes occur in four clusters, HOX A to D, on chromosomes 7, 17, 12, and 2, respectively. *HOXA* and *HOXB* genes are expressed in CD34+ cells and downregulated as these cells mature. Intriguingly, murine bone marrow cells engineered to overexpress Hoxb4 by retrovirus-mediated gene transfer show a dramatic upregulation in stem cell activity both in vitro and in vivo, although it may not be required for normal hematopoiesis.[570,571] Serial transplantation studies showed a greatly enhanced ability of *Hoxb4*-transduced bone marrow cells to regenerate the most primitive HSC compartment, resulting in fiftyfold-higher numbers of transplantable totipotent HSCs in primary and secondary recipients, compared with serially passaged control cells. This in vivo expansion of *Hoxb4*-transduced HSCs was not accompanied by identifiable anomalies in the blood of these mice, suggesting that Hoxb4 is an important regulator of very early but not late hematopoietic cell proliferation. Recent data show that ectopic expression of Hoxb4 in yolk sac and embryonic stem cells confers long-term engraftment capacity in primary and secondary recipients.[572] Daley and colleagues[573] reported that nuclei from *Rag2* knockout ($\mathrm{Rag2}^{-/-}$) tail cells could be transferred into enucleated oocytes, and embryonic stem (ntES) cell lines could be derived from the resulting blastocysts. The Rag2 mutation was then corrected by homologous recombination. Insertion of Hoxb4 into the corrected embryonic stem cells allowed their expansion into transplantable HSCs. These cells were able to partially correct the defect in immunoglobulin production in $\mathrm{Rag2}^{-/-}$ recipients after bone marrow transplantation.[573] The HOX pathway has been expanded to include HOX A7 and A9 as major regulators of hematopoiesis and leukemia formation.[574] The posterior *Hox* genes therefore drive HSC production; this was highlighted by the finding that mutants of Cdx4, a controller of *HOX* gene expression, lack HSCs in the zebrafish and Cdx controls *Hox* gene expression for the formation of HSCs.[570]

The *Gfi1* locus was originally identified as an oncogene causing lymphoma based on retroviral insertion.[575] Gfi1 contains an internal SNAG domain and a six–zinc-finger DNA-binding domain. There are two nearly identical genes called *Gfi1* and *Gfi1b*. Gfi1 is restricted to the lymphoid system and neutrophils, whereas Gfi1b seems to be distributed throughout the entire hematopoietic system. *Gfi1* knockout animals have a severe reduction in lymphoid progenitors. This leads to an early lack in both CD4+ and CD8+ cells. In addition, IL-7 receptor signaling is suppressed. Gfi1 is a major regulator of neutrophil maturation. Normal neutrophils are absent in the knockout animals but eosinophils are present in normal numbers. The response of neutrophils to G-CSF is preserved, but differentiation does not occur. There is a significant interaction of Gfi1 with other transcription factors, including PU.1, Cebpβ, and Cebpε, which regulate neutrophil maturation.

Gfi1 also has been shown to be involved in HSC self-renewal. *Gfi1* knockout animals actually increase and outcompete other cells. This leads to stem cell exhaustion. Gfi1b may also regulate stem cell homeostasis. The HSCs appear to be more active in terms of their cell cycle and have increased proliferation rates. It is clear that p21 is likely one of the mediators of Gfi1 in HSC production.[576] There is also modulation of the STAT3 activity as a consequence of the interaction of Gfi1 with PIAS-3, a factor that simulates transcription factors. This is interesting because other genes such as *Tal1*, *Runx1*, *Notch 1*, *Notch 2*, *RBPJ*, integrin-1, *Hoxb4*, and β-catenin (*CTNNB*) are dispensable for most HSC activities, whereas p21 (*CDKN1A*), Bmi 1, tel1, Cebp, PU.1, and Gfi are actually required.

Growth Factors and Stem Cells

HGFs also appear to influence at least some classes of stem cells. Analysis of the actions of HGFs on "purified" murine or human stem and progenitor cells has led to several major conclusions. These conclusions should be interpreted in light of the fact that, to date, even the most highly purified "stem cell" fractions are still heterogeneous with respect to content of LTR-HSC, HSC with short-term reconstituting potential, and lineage-committed progenitors. HGFs such as SCF and perhaps IL-3, GM-CSF, and G-CSF can independently support the survival of murine and/or human stem cell populations.[297,577-579] Of all of these HGFs, however, only SCF has been shown to enhance the survival of murine LTR-HSCs, and no single HGF or combination of HGFs has unequivocally shown the capacity to induce significant self-renewal of LTR-HSCs.[580,581] Mice deficient in IL-6 show a reduction in CFU-S and IL-$6^{-/-}$ bone marrow cells fail to contribute to long-term hematopoiesis after serial transfer.[329] In addition to its effect on megakaryocyte and platelet formation, TPO is also vital for stem cell production. Mice that lack the receptor for TPO, Mpl, show reduced numbers of blast colonies and CFU-S, and fail to compete effectively with normal stem cells for reconstitution of hematopoiesis in irradiated recipients, even when transplanted in tenfold excess.[582] Furthermore, both murine and human repopulating activity segregates with primitive cells that express MPL.[583] In the human system, information on HSC self-renewal is not available, because no human assay measures this property.

Analysis of mutations that affect the function of stem cells and the hematopoietic microenvironment through HGF interactions has provided important insights. Two murine mutations have been characterized in some detail, the Steel (Sl) and dominant white spotting (W) mutations.[591,520,564] Genetically affected mice that are defective at these loci have a severe macrocytic anemia associated with increased radiation sensitivity, lack of pigmentation, poor gastrointestinal motility, and sterility. Although phenotypically similar, these mutations map to different chromosomes (W to chromosome 5, Sl to chromosome 10) and have distinct hematologic characteristics. The W mutation, which is best characterized at the molecular level, results in a functional deficiency of HSCs and, particularly, erythroid progenitors. Transplantation of normal bone marrow into homozygous W recipients completely corrects the hematopoietic abnormalities, whereas transplantation of W bone marrow into normal mice fails to reconstitute hematopoiesis.[591,584] The W gene is allelic with the Kit protooncogene,[585,586] which, as discussed above, is known to be a member of a tyrosine kinase receptor family.[587] Several variants of the W mutation have been shown to be phenotypic expressions of specific mutations of the *Kit* gene, and the severity of the phenotypic changes associated with specific alleles correlates with the degree of functional impairment of kinase activity.[588]

In contrast, the Steel mutation affects the function of the cells of the microenvironment. Sl/Sl^d bone marrow cells are capable of reconstituting hematopoiesis in irradiated normal mice, whereas transplantation of normal bone marrow into Sl/Sl^d animals fails to cure the defect.[589] A deeper insight into the molecular nature of this defect was provided by the purification of a factor that is active on mast cells and on mouse bone marrow that has been exposed to 5-FU (enriched for primitive stem cells but depleted of mature progenitors).[590,591] Labeling studies with the purified recombinant protein demonstrate that it is the ligand for Kit.[592-595] Furthermore, administration of the factor to Sl/Sl^d mice corrects their macrocytic anemia and repairs their mast cell deficiency. Less severe mutations at the Sl locus, such as Sl^d, are associated with smaller deletions at the Sl locus. The gene encodes a protein that exists in both transmembrane and secreted forms.[592,596,597] Recent studies have shown that SCF is expressed by HSCs and perivascular stromal cells in the marrow niche, but expression by endothelial cells and leptin receptor perivascular cells is critical for HSC survival.[37]

Recently, other growth factor pathways that are important during embryogenesis and have been subverted in certain cancers have also been implicated in stem cell self-renewal. Notch receptors (four members, Notch 1 to 4) are expressed on the surface of a variety of hematopoietic cells as proteolytically cleaved dimers comprising an EGF-repeat–rich extracellular domain and a transmembrane/intracellular domain that contains two motifs (RAM and ANK) that can bind to a transcriptional repressor CBF1/RBPJκ (see Kojika and Griffin[598] for a detailed review). After ligand binding (three ligands, Delta, Jagged1, and Jagged2), the transmembrane/intracellular domain is cleaved to release the active intracellular domain of Notch (ICN), which translocates to the nucleus, binds to CBF1/RPBJκ, and transactivates genes such as Hairy and Enhancer of Split (HES)-1, a bHLH protein that suppresses transcription of N-box (CACNAG) target genes. Human Notch 1 was first identified as a gene called *TAN-1* that is involved in some T-cell leukemias, in which it generates an intracellular activated form of Notch 1 (ICN-1).[599] Remarkably, overexpression of ICN-1 in murine stem cells leads to immortalization of cytokine-dependent cell lines that can generate lymphoid or myeloid progeny in vitro and in vivo, suggesting a role for Notch 1 in stem cell self-renewal.[600] Activating mutations in Notch have been found in many T-cell leukemias.[601] Addition of soluble Jagged1 to cultures of human purified stem and progenitor cells also increased NOD/SCID repopulating activity.[602] A clinical trial was recently completed using soluble Delta as a means of expanding hematopoiesis in vitro. Cord blood was treated with the soluble Delta, and the expanded progenitors were then infused into the patient. There was no effect on stem cells. This treatment enhanced neutrophil recovery following preparative chemotherapy and irradiation.[603]

A second signaling pathway that may be involved in stem cell self-renewal involves the Sonic hedgehog[604] protein. Shh activates the Smoothened receptor (Smo) by binding to Patched, its inhibitor. Smo initiates signaling that regulates transcription factors of the Gli family, which modify expression of genes that encode BMP-4 and its inhibitor Noggin. Shh has recently been shown to induce expansion of human NOD/SCID repopulating cells, possibly through regulation of BMP-4. Last, Wnt signaling may also be involved in stem cell self-renewal. Wnt signals through the receptors Frizzled and lipoprotein receptor–related protein (LRP) to activate a cytoplasmic protein called *Dishevilled,* which in turn stabilizes β-catenin, a transcriptional coactivator that associates with the Tcf/LEF family of transcription factors.[605] Without Wnt signaling, β-catenin is normally destabilized by a cytoplasmic complex that comprises Axin, adenomatous polyposis coli, and glycogen synthase kinase 3β (GSK-3β). Overexpression of activated β-catenin in highly purified murine HSCs appears able to expand the pool of transplantable cells.[606] Controversy still exists about the role of wnt signaling during homeostasis, but it seems to have a role during stress. Mammalian target of rapamycin (mTOR) may cooperate with wnt at homeostasis.[607] The wnt pathway established different responses based on level of activation.[608]

Two models have been proposed to explain the mechanisms that influence the choice of stem cells between self-renewal and commitment. A *stochastic model* was proposed by Till, McCullough, and Siminovitch.[511] In this model, self-renewal or differentiation is considered to occur in a random or stochastic manner, dictated only by a certain probability. Because no extrinsic source of stem cells exists, under steady-state conditions the overall probability of stem cell division resulting in self-renewal must be 0.5; probabilities less or greater than this value would lead to progressive stem cell depletion (aplasia) or expansion (leukemia), respectively. The commitment of stem cells could occur symmetrically, where overall, half the stem cells divide to produce progeny both of which enter a differentiation pathway, and the other half of the stem cells generate progeny that are both stem cells. Alternatively, asymmetric division would give rise to one stem cell and one cell committed to differentiate. Analysis of single cells from blast cell colonies has shown that hematopoietic cells can divide asymmetrically; these micromanipulated single cells give rise to colonies that comprise almost all possible lineage combinations.[111] Single-cell analysis of purified human CD34+CD45RA^{lo}CD71^{lo} provides evidence for quiescent survival, self-renewal, and asymmetric division.[609] These data provide support for a stochastic mechanism to explain both commitment and restriction of differentiation potential. The best purification strategies still allow only one of two cells to be an HSC, and paired daughter analysis has some caveats with regard to lineage tracing. During the regeneration of hematopoietic tissues after injury by irradiation or cytotoxic drugs, the probability of generating stem cells must increase. How this probability is altered is one of the outstanding unanswered questions in hematopoiesis.

The osteoblastic niche in bone marrow plays a role in stem cell self-renewal, whereas the sinusoidal endothelial niche regulates proliferation, differentiation, and mobilization. These functional differences suggest a mechanism for the external control of stem cell expression. This observation and others related to the morphology of the focal development of hematopoietic islands attached to adherent cells have led to postulation that HSCs reside within stromal cell "niches" that play a vital role in supporting stem cell survival, perhaps by intimate cell contact (see Fig. 1-5).[15] Interestingly, a recent study showed that deletion of Dicer1, an RNAseIII endonuclease important for microRNA biogenesis, in osteoprogenitors led to myelodysplasia (MDS) and acute myeloid leukemia (AML). Most intriguing, the dysplastic or leukemic hematopoietic cells retained Dicer1 expression. Subsequent gene expression studies showed reduced expression of the *SBDS* gene, which is mutated in 90% of patients with Shwachman-Diamond syndrome, who also have an increased risk of development of MDS and AML. Thus this study suggests, surprisingly, that stromal cell dysfunction may have an important role in secondary oncogenesis.[610]

Whether a stochastic mechanism or one influenced by environmental cues dictates the outcome of the stem cell decision to commit to one or the other hematopoietic lineage is also uncertain. Recent experiments suggest that cross-antagonism among lineage-specific transcription factors may provide a mechanistic explanation for lineage specification. Forced expression of the erythroid-specific factor GATA1 in myelomonocytic cells perturbs their ability to differentiate,[611] and evidence is accumulating that this is due to direct physical interaction and cross-antagonism of PU.1, the myeloid transcription factor, and GATA1; GATA1 inhibits PU.1 by preventing it from interacting with its cofactor JUN, whereas PU.1 prevents GATA1 from binding to DNA.[612-615] In Down syndrome patients, there are mutations in GATA1, which lead to a truncated protein missing its N-terminus.[616] This appears to give competitive advantage to a yolk sac/fetal liver progenitor in the genesis of leukemia and transient myeloproliferative disorder. Another example is the antagonism between FOG1 and C/EBP-β in an eosinophilic cell line, in that enforced expression of FOG1 blocks C/EBP-β mediated eosinophil differentiation.[617] It is possible that lineage-specific transcription factors not only have potent inductive effects but also exert blocking effects on alternate lineage choices. The observation that forced expression of C/EBP-β in pancreatic cells promoted their differentiation into a hepatic phenotype raises the intriguing possibility that this mechanism underlies stem cell plasticity as well[618] (reviewed by Cantor and Orkin[541]).

Erythropoiesis

It is well established that the level of oxyhemoglobin and the rate of delivery of oxygen to the tissues is the fundamental stimulus of erythropoiesis.[5] In species that package hemoglobin in erythrocytes, erythropoietin mediates the response to oxygen demand and does so by interacting with specific receptors[619] that are found on the surface of committed erythroid progenitor cells[620-622] and erythroblasts.[623] Insight into the mechanism by which hypoxia induces a transcriptional increase in the expression of the *Epo* gene has come from the identification of the hypoxia-inducible transcription factor HIF-1α.[387,624]

It is believed that BFU-E do not directly give rise to erythroblasts in vivo except under conditions of extreme anemic stress. Instead, they mature to single erythroid colony-forming units, or CFU-E, which divide in vivo. Under the influence of lower concentrations of erythropoietin these CFU-E form single, relatively small colonies of proerythroblasts at about 1 week in vitro. Many (at least half) of CFU-E will form erythroid colonies in vitro in response to erythropoietin alone. They do not require the additional presence of either GM-CSF or IL-3, having differentiated beyond this requirement.[625] All proerythroblasts can differentiate in the presence of erythropoietin alone. In the steady state, the number of human CFU-E exceeds the number of BFU-E by a factor of 10. CFU-E are larger than BFU-E, and because a higher fraction of CFU-E are in the S phase of DNA synthesis than are BFU-E, the former exhibit a higher rate of "suicide" in response to exposure to tritiated thymidine. The membranes of mature BFU-E and CFU-E are CD34+ and HLA-DR+, and various negative and positive selection methods may be used to purify them from sources such as bone marrow and human fetal liver.[125,626] They have the appearance of lymphoblasts.

The bone marrow of an adult mouse contains about 500 CFU-E per 10^5 nucleated cells. In response to anemic stress, as in hemorrhage or hemolysis, nearly the entire burden of accelerated reticulocyte production is borne by the rapid erythropoietin-dependent influx into the proerythroblast pool from the progenitor compartment.[124,135] This produces an expanded proerythroblast pool. Little or no increase in the mitotic rate of recognizable erythroid precursors occurs.[124] Instead, the late BFU-E and CFU-E proliferate in response to the engagement of their erythropoietin receptors by the hormone and, as well, differentiate to proerythroblasts and beyond. In normal murine marrow, following experimental hemorrhage or hemolysis, the CFU-E frequency of about 500 per 10^5 nucleated cells increases to 1000 to 2000 CFU-E per 10^5 nucleated cells. In contrast, hypertransfused mice exhibit a reduced number of CFU-E per 10^5 nucleated marrow cells (values between 10% and 20% of normal have been reported).

During stress erythropoiesis induced by anemia, the orderly progression from immature BFU-E through CFU-E to proerythroblast is interrupted as high erythropoietin levels appear to permit or induce differentiation of immature progenitors to proerythroblasts. In the rhesus monkey this premature terminal differentiation may account for the marked increase in fetal hemoglobin content and F cells seen in simian stress erythropoiesis.[627] The ability of human progenitors to generate erythroblasts capable of synthesizing large quantities of fetal hemoglobin is less pronounced.[628] Thus the accumulation of F cells in peripheral blood in response to anemia is relatively small.[629] Such red cells are usually macrocytic and carry the i antigen as well, but these two characteristics may relate to a short transit time through the marrow in response to erythropoietin rather than to an intrinsic characteristic of fetal hemoglobin-containing cells themselves (see below). F cells are also present in very small numbers in the blood of normal individuals, but these cells are not macrocytic and do not bear i antigen. F cell progenitors can be detected easily in the bone marrow of patients with various hemoglobinopathies[630,631] and even in normal marrow.[632]

Transcription Factors and Erythropoiesis

As discussed above, targeted disruption of the *Tal1*, *Lmo2*, and *Gata2* genes leads to embryonic lethality because of failure of blood production, probably at the level of the HSC. GATA1 expression is limited to multipotent progenitors and erythroid, megakaryocyte, mast, and eosinophil lineages.[120,633,634] Analysis of chimeric mice injected at the blastocyst stage with $Gata1^{-/-}$ embryonic stem cells shows a failure of a contribution of the $Gata1^{-/-}$ cells to erythrocytes but development into other hematopoietic lineages, as well as other tissues.[635,636] Differentiation assays in vitro show proerythroblast arrest and apoptosis of these cells.[637-639] A transcriptional cofactor of GATA1, Friend of GATA1 (FOG1), was discovered and found to be essential for erythropoiesis and megakaryopoiesis.[640,641] Evidence that this interaction is essential in vivo comes from studies of a family with severe dyserythropoietic anemia and thrombocytopenia. Affected family members have a mutation in GATA1 that disrupts its interaction with FOG1 without affecting DNA-binding affinity.[642] The EKLF transcription factor was found as an activity bound to the CACCC site of the β-globin promoter.[643] It controls globin expression and some aspects of erythroid development. The NF-E2 protein complex binds to the locus control region (LCR) to regulate globin gene transcription; it is a dimer of a tissue-restricted (erythroid/megakaryocyte/mast cell) cnc domain subunit of 45 kD and a smaller, widely expressed subunit of 18 kD, and is essential for platelet, but not erythrocyte, production.[644,645]

Growth Factors and Erythropoiesis

The regulation of the proliferation and maturation of erythroid progenitors depends on interaction with a number of growth factors. The availability of pure recombinant growth factors, the enrichment of target progenitor cells, and the use of defined "serum-free" culture conditions have provided insights into the role of these factors during hematopoiesis.

Erythropoietin (EPO) is essential for the terminal maturation of erythroid cells. Its major effect appears to be at the level of the CFU-E during adult erythropoiesis, and recombinant preparations[625] are as effective as the natural hormone.[646,647] These progenitors do not require "burst-promoting activity"[648,649] in the form of IL-3 or GM-CSF, and their dependence on EPO is emphasized by the observation that they will not survive in vitro in the absence of EPO. Because most CFU-E are in cycle, their survival in the presence of EPO is probably tightly linked to their proliferation and differentiation to mature erythrocytes. EPO also acts on a subset of presumptive mature BFU-E, which also require EPO for survival and terminal maturation. A second subset of BFU-E, presumably less mature, survive EPO deprivation if IL-3 or GM-CSF (IL-3 more than GM-CSF) is present. When EPO is added to these cultures on day 3 these BFU-E form typical colonies. Under serum-deprived culture conditions the combination of IL-3 and GM-CSF results in more BFU-E than either factor alone when EPO is added on day 3.[650] Although EPO is crucial for the terminal differentiation of erythroid progenitors, mice with homozygous null mutations of the *Epo* or *Epor* genes form BFU-E and CFU-E normally, but they fail to differentiate into mature erythrocytes.[327] Both the $Epo^{-/-}$ and $Epor^{-/-}$ mutations are embryonically lethal due to failure of definitive (fetal liver) erythropoiesis. However, yolk sac erythropoiesis is only partially impaired, indicating that a population of EPO-independent primary erythropoietic precursors exists. SCF has marked synergistic effects on BFU-E cultured in the presence of EPO,[152] although alone it has no colony-forming ability. SCF is crucial for the normal development of CFU-E, because mice that lack SCF (Steel mutants) or its receptor Kit (W mutants) are severely anemic and show a reduction in fetal liver CFU-E.[651] Further studies showed that SCF induces tyrosine phosphorylation of the EPOR and that Kit associates with the cytoplasmic domain of the tyrosine phosphorylated EPOR. Further insight into the molecular mechanism by which Epo prevents apoptosis in erythroid cells comes from studies of $Stat5a^{-/-}5b^{-/-}$ mice. During fetal development the embryos are severely anemic; the erythroid progenitors in fetal liver are reduced in number and show increased apoptosis.[652] This result was explained by the finding that STAT5 mediates the early induction of the antiapoptotic gene $Bcl\text{-}X_L$ through direct binding to its promoter. Interestingly, although adult animals were thought to be hematologically normal, about half have chronic anemia with splenomegaly, due to an increase in early erythroid precursors; erythropoiesis is ineffective because of an increase in apoptosis in these early normoblasts that show reduced levels of Bcl-X_L.[653]

Factors distinct from the classic CSFs may positively regulate erythropoiesis, either directly or indirectly. Limiting-dilution studies of highly purified CFU-E in serum-free culture show that insulin and insulin-like growth factor 1 (IGF-1) act directly on these cells.[654] The presence of Epo is essential in these studies, which contrast with earlier murine studies of unfractionated cells in which CFU-E respond to IGF-1 or insulin in the absence of Epo.[655] Activin is another factor that enhances both BFU-E and CFU-E colony formation. This protein dimer, also known as *follicle-stimulating hormone–releasing protein,* appears to have a lineage-specific effect on erythropoiesis that is indirect because removal of monocytes and/or T lymphocytes abrogates its effect.[656] It is interesting that activin has been identified as the factor produced by vegetal cells during blastogenesis that induces animal ectodermal cells to form primary mesoderm.[657] Hepatocyte growth factor has also been shown to have synergistic effects on CFUs-GEMM and BFU-E in cultures containing EPO.[658]

Negative Regulation of Erythropoiesis

Observations that subsets of lymphocytes with an immunologic suppressor phenotype isolated from normal subjects can inhibit erythroid activity in vitro[659-661] correlate with reports of patients with a variety of disorders in whom anemia or granulocytopenia is associated with an expansion of certain T-lymphocyte populations (see also Chapter 7).[662-664] In the rare disorder T lymphocytosis with cytopenia,[665] in vitro suppression of erythropoiesis has been correlated with the expansion of a T-lymphocyte population that may be the counterpart of the hematopoietic suppressor cells isolated from normal blood. The phenotype of these cells has been described in detail.[665,666] The cell is a large granular lymphocyte that is positive for both E rosettes and CD8 (classic suppressor phenotype). Suppressor T cells may also be involved in some cases of aplastic anemia[667,668] or neutropenia[669] without an underlying immunologic disorder or an overt T-cell proliferation. Exactly how such suppressor T cells interact with hematopoietic progenitors and what surface antigens are "seen" by the suppressors is uncertain. There is evidence to support the concept that suppression of erythroid colony expression in vitro is regulated by T cells and may be genetically restricted.[666,670] Cell-cell interactions in immunologic systems have been well characterized with regard to surface determinants that allow for cellular recognition. That certain phenotypes of T cells "recognize" distinct classes of histocompatibility antigens on immunologic cell surfaces has been well described.[671] Thus the observation that hematopoietic progenitors have a unique distribution of class II hiscompatibility antigens on their cell surfaces[672-675] suggests a role for these antigens in the cell-cell interactions that regulate hematopoietic differentiation.

TNF also suppresses erythropoiesis in vitro.[676,677] The injection of peritoneal macrophages into Friend murine leukemia virus–infected animals results in rapid but transient resolution of the massive erythroid hyperplasia associated with this disease. This may be due to elaboration by macrophages of IL-1α, which does not suppress erythropoiesis itself but acts by the induction of TNF. This effect is reversed by Epo.[678]

Myelopoiesis

Phagocyte Development

Although a clonogenic assay of granulocyte progenitors was developed almost a decade before the erythroid clonogenic assay, the various factors responsible for granulocyte-macrophage development remain incompletely understood. Excellent reviews of early work in this field have been provided by Metcalf[679] and Moore.[117]

It is now accepted that the granulocyte-macrophage colony-forming unit, or CFU-GM, is derived from the pluripotent progenitor and, under the influence of SCF, IL-3, GM-CSF, G-CSF, and/or M-CSF, ultimately gives rise to mature granulocytes and monocytes. Monocytes irreversibly leave the circulation[680,681] and differentiate further into fixed-tissue macrophages, a category comprising the alveolar macrophages,[682] hepatic Kupffer cells,[683] dermal Langerhans cells,[684] osteoclasts,[685] peritoneal and pleural macrophages, and, perhaps, brain microglial cells.[686] The enormous diversity of this system and the high turnover rate of granulocytes, as well as the necessity of maintaining splenic, marginated, and bone marrow granulocyte pools in order to meet sudden demands caused by infection, have led to the evolution of an extremely complex regulatory network.

Granulopoiesis associated with myelosuppression, cyclic neutropenia, and infection depends on IL-23 production by macrophages and dendritic cells that in turn stimulates IL-17 and G-CSF upregulation, a pathway revealed by study of leukocyte adhesion molecule–deficient mice.[687] Recent data suggest that the innate immune mechanisms that involve Toll-like receptor 4 (TLR4) and its adaptor protein TRIF may be important in steady-state and emergency granulopoiesis.[688]

Transcription Factors and Myelopoiesis

A family of transcription factors important for commitment to myeloid and lymphoid lineages as well as regulation of myeloid-specific promoters such as those of the myeloperoxidase (MPO) and neutrophil elastase (NE) genes are factors that were first identified on the basis of their ability to bind to the polyomavirus enhancer–binding protein 2/core binding factor (PEBP2/CBF). Two alpha subunits (CBFα1 and CBFα2 [the human homologue is known as *AML-1* or *RUNX1*]) bind DNA with low affinity, and affinity is strengthened in the presence of the non–DNA-binding beta subunit (CBFβ). As noted above, runx1$^{-/-}$ mice die in utero by day 12.5 because of failure of production of all definitive hematopoietic lineages.[568] The CCAAT/enhancer-binding protein (C/EBP) family of transcription factors bind to DNA through a basic region–leucine zipper domain (bZIP). There are several family members (C/EBPα, C/EBPβ (NF–IL-6), C/EBPγ, C/EBPδ, C/EBPζ, and C/EBPε) that are differentially expressed during myelopoiesis, with increasing (C/EBPβ), or an increase followed by either a partial (C/EBPδ) or a marked (C/EBPα) reduction in level of, expression during maturation of 32D cl3 cells to terminally differentiated granulocytes.[689] C/EBPα has been implicated in the regulation of hepatocyte and adipocyte differentiation (levels are low in undifferentiated dividing cells but high in quiescent terminally differentiated cells), and also in myeloid CSF receptor promoter function; RUNX1 can act synergistically with C/EBPα to activate the M-CSFR promoter.[690] *C/ebpα*$^{-/-}$ mice show arrested myelopoiesis at the myeloblast stage resulting from failure of expression of G-CSF and IL-6 receptors.[691,692] Mice that lack C/EBPβ produce monocytes that are defective in bactericidal and tumoricidal function; their macrophages and fibroblasts, but interestingly not their endothelial cells, fail to produce G-CSF in response to LPS.[693] Thus C/EBPβ is important for "emergency" granulopoiesis.[694] C/EBPε is produced primarily in myeloid lineages. Knockout mice are viable and fertile but die at 50 to 75 days from opportunistic infections with *Pseudomonas aeruginosa*.[695] Nullizygous animals fail to produce normal neutrophils and eosinophils. Functional abnormalities include diminished release of hydrogen peroxide in response to phorbol myristate acetate (PMA) stimulation, because of failure to produce secondary and tertiary granules, which are important reservoirs of membrane-bound components of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase apparatus. Additional components of secondary and tertiary granules, lactoferrin and gelatinase B, are absent because of failure of transcriptional activation of C/EBPε.[695,696] Interestingly, similar abnormalities characterize the rare neutrophil-specific granule deficiency,[697] and indeed mutations in *C/EBPε* have recently been found in these patients.[698-700] The PU.1(Spi-1) transcription factor is a member of the Ets family and is expressed principally in monocytes/macrophages and B lymphocytes, and also in erythroid cells and granulocytes.[701,702] Potential target genes include the integrin CD11b, M-CSFR, GM-CSFRα, G-CSFR, and the Igλ light chain.[703-707] Mice that lack PU.1 die in utero with absence of monocytes, granulocytes, and T and B lymphocytes; anemia is variable and thus does not explain the prenatal mortality.[708]

Growth Factors and Myelopoiesis

Murine IL-3 stimulates a broad spectrum of myeloid progenitor cells, including pluripotent stem cells, granulocyte and/or macrophage colony-forming cells or units (CFU-GM, CFU-G, and CFU-M), erythroid burst-forming units (BFU-E), eosinophil colony-forming units (CFU-Eo), megakaryocyte colony-forming units (CFUs-Meg), and mast cells. As its name implies, GM-CSF was initially shown to be more restricted as a stimulus of the proliferation and development of CFU-GM. However, murine studies with purified or recombinant factor have shown that it stimulates the initial proliferation of other progenitors such as BFU-E as well (see above).[209,709] The other murine factors, G-CSF and M-CSF, are more restricted and predominantly stimulate granulocyte and monocyte colony-forming units (CFU-G and CFU-M), respectively.[710,711]

With the possible exception of GM-CSF, the activities of the human CSFs are similar to those of the corresponding murine factors. Both IL-3 and GM-CSF affect a similar broad spectrum of human progenitor cells. This includes CFU-GEMM, CFU-GM, CFU-G, CFU-M, CFU-Eo, and CFU-Meg. In full-serum cultures, IL-3 and GM-CSF alone stimulate the formation of colonies derived from CFU-GM, CFU-G, CFU-M, CFU-Eo, and CFU-Meg. Data from serum-free cultures suggest that in the presence of IL-3 or GM-CSF alone, myeloid colony formation is much reduced, and that optimal CFU-G or CFU-M proliferation requires the addition of G-CSF or M-CSF, respectively, to the cultures.[213,650] Even in serum-replete conditions, IL-3 acts additively or synergistically with G-CSF to induce more granulocyte colony formation than is observed with either factor alone.[212]

Insight into the in vivo role of GM-CSF comes from studies in which the GM-CSF gene was disrupted by homologous recombination in embryonic stem cells.[341] GM-CSF knockout mice showed normal basal hematopoiesis but developed progressive accumulation of surfactant lipids and proteins in the alveolar space, the defining characteristic of idiopathic human pulmonary alveolar proteinosis. Extensive lymphoid hyperplasia associated with lung airways and blood vessels was also found. Surfactant proteins and lipids are synthesized by type II pneumocytes and cleared from the alveolar space by type II cells and by alveolar macrophages. The lungs from the null animals showed normal surfactant synthetic capacity and no accumulation in type II pneumocytes. In contrast, the alveolar macrophages showed a marked increase of surfactant protein and lipid, suggesting strongly that these cells cannot process surfactant as a result of the lack of GM-CSF. Mice that were generated with null mutations of the common chain of the GM-CSF/IL-3/IL-5 receptor (βc) show similar pulmonary pathology, and also show low basal numbers of eosinophils and absence of blood and lung eosinophilia in response to infection with the parasite *Nippostrongylus brasiliensis*.[341a] The G-CSF gene has also been disrupted by homologous recombination in embryonic stem cells.[317] G-CSF$^{-/-}$ mice have a chronic neutropenia (20% to 30% of normal levels) and reduced bone marrow myeloid precursors and progenitors. The animals also had a markedly impaired capacity to increase neutrophil and monocyte counts after infection with *Listeria monocytogenes*.

In addition to their effects on progenitor differentiation, the CSFs also induce a variety of functional changes in mature cells. GM-CSF inhibits polymorphonuclear neutrophil migration under agarose,[713] induces antibody-dependent cytotoxicity (ADCC) for human target cells,[714] and increases neutrophil phagocytic activity.[207] Some of these functional changes may be related to GM-CSF–induced increase in the cell surface expression of a family of antigens that function as cell adhesion molecules.[715] The increase in antigen expression is rapid and is associated with increased aggregation of neutrophils; both are maximal at the migration inhibitory concentration of 500 pM, and granulocyte-granulocyte adhesion can be inhibited by an antigen-specific monoclonal antibody. GM-CSF also acts as a potent stimulus of eosinophil ADCC, superoxide production, and phagocytosis.[716] G-CSF acts as a potent stimulus of neutrophil superoxide production, ADCC, and phagocytosis,[717] whereas M-CSF activates mature macrophages[718] and enhances macrophage cytotoxicity.

Megakaryocytopoiesis

The cloning of thrombopoietin (TPO) has greatly clarified our understanding of the regulation of megakaryocytopoiesis.[197] Prior to the discovery of TPO, several factors,[719] including IL-3,[720] IL-6,[721] IL-11,[722] SCF,[723,724] and even erythropoietin[725,726] were shown to stimulate megakaryocytopoiesis and thrombopoiesis in vitro and in vivo. IL-3, IL-6, and IL-11 engage heterodimeric receptors of the beta common family (IL-3R) and gp130 family (IL-6R and IL-11R). SCF engages a receptor the intracellular domain of which expresses tyrosine kinase activity upon ligand binding. As already emphasized in this chapter, ligand engagements of these receptor families are known to induce early multipotent progenitors to proliferate and even differentiate toward lineage-specific progenitors, and SCF, IL-3, and IL-11 participate in the induction of the proliferation and differentiation of lineage-specific progenitors. Single-cell analysis of prospectively isolated murine megakaryocyte progenitors shows that a large proportion (≈60%) express EPOR,[113] which is consistent with the potent effect of EPO on megakaryocyte colony formation.[727]

The discovery of TPO provides a major step in understanding megakaryocytopoiesis because this factor induces lineage-restricted megakaryocyte progenitor proliferation, differentiation of those committed progenitors to megakaryoblasts, and, finally, differentiation of megakaryoblasts to the megakaryocytes that in turn produce platelets.

Thrombopoietin

TPO is produced at the site of hematopoiesis. Therefore, though its activity is increased in the blood during episodes of thrombopenia, it does not necessarily function as a hormone, because it is produced directly at the site of thrombopoiesis. In this sense, it differs from erythropoietin, which is not produced at all in marrow stroma. Blood levels may increase in thrombopenic states merely because circulating platelets and/or tissue megakaryocytes sop up the growth factor and carry it out of the circulation.[399,728] This theory has received support from observations in mice with disruption of the murine transcription factor gene called *NF-E2*;[122] although these animals are thrombocytopenic they have an increase in megakaryocyte mass and no increase in serum TPO levels.[729]

As reviewed by Kaushansky,[197] the TPO molecule is considerably longer than the other HGF polypeptides. Its 5′ half bears 23% sequence homology to erythropoietin, whereas the 3′ half bears no structural homology to any cytokine and may be removed by a proteolytic mechanism. Indeed, removal of this half does not ablate physiologic function. The resemblance of the 5′ domain of the molecule to erythropoietin may explain the synergy of thrombopoietin and erythropoietin in megakaryocyte colony formation and platelet production.[197,719] It is well-recognized that splenectomized individuals with persistent anemia usually have significant thrombocytosis and many individuals with red cell aplasia and high EPO levels also have thrombocytosis and megakaryocytosis.

The function of TPO has been studied carefully in vivo and in vitro. Lineage-specific CD34+ meg progenitors bear receptors for SF, IL-3, IL-11, and TPO, the four major classes of hematopoietic cytokine receptors. Maximal megakaryocyte colony formation probably requires signaling by all four receptors, but TPO is absolutely required for the final stages of CFU-MEG maturation, including maximal ploidy and cytoplasmic volume, and, therefore, platelet production. Therapeutic trials of TPO in mice have shown that TPO is species specific. Treatment of mice with murine TPO induces massive thrombocytosis, whereas human TPO is much less active in these animals. More importantly, TPO is active in reducing the platelet nadir in mice and primates rendered thrombopenic by chemotherapy or irradiation.

Circulating Platelets

The differential diagnosis of thrombocytopenia rests first on evaluation of platelet morphology. In conditions in which megakaryocytopoiesis is accelerated, circulating platelet volume (and usually diameter) is increased. The reasons for this shift in volume are disputed. Some claim that young platelets are larger than old platelets.[730] Others suggest that large megakaryocytes give rise to large platelets.[731] Neither explanation satisfies all experimental and clinical conditions, but in general thrombocytopenia secondary to increased destruction of platelets is associated with platelets of large volume, and thrombocytopenia related to decreased production of platelets is associated with platelets of normal size. There are major exceptions to this rule. Patients with hyposplenism tend to have large platelets in their blood, whether thrombopoiesis is increased or not, and patients with primary abnormalities of platelet function, such as Wiskott-Aldrich syndrome or Bernard-Soulier syndrome, have platelet sizes that bear no relationship to platelet production. Thrombopoietin increases platelet production by increasing both the number and size of individual megakaryocytes. Though TPO is probably solely responsible for the later stages of recognizable megakaryocyte differentiation and proliferation of megakaryocyte progenitors, its function depends, at least in part, on the additional stimulation of megakaryocyte progenitors (and probably early megakaryocytes as well) with other growth factors, including IL-3, IL-11, SF, and EPO.

CLINICAL USE OF HEMATOPOIETIC GROWTH FACTORS

Correction or amelioration of marrow failure syndromes by administration of HGFs has been and continues to be a major practical goal of research in hematopoiesis. The goal could not be achieved, however, until recombinant DNA technology provided sufficient amounts of the hormones to permit interpretable investigations.

Human Clinical Studies

Several recombinant HGFs are currently under evaluation or used in a variety of clinical settings. G-CSF and erythropoietin are widely used clinically. G-CSF shortens the hypoplasia that follows chemotherapy and makes more intensive myeloablative chemotherapy regimes possible.

Malignant Disease

G-CSF. In the first phase I/II clinical studies in patients with malignant disease, administration of G-CSF by bolus or continuous intravenous (IV) infusion for 5 to 6 days before chemotherapy led to a dose-related increase in polymorphonuclear neutrophils.[732,733] Rapid increases in neutrophil counts were observed, with maximal counts of 80 to 100 × 10^9/L at doses of 10 to 30 mg/kg/day. A transient depression in neutrophil counts was noted to precede this increase in one study.[734] A double-blind, randomized, placebo-controlled multicenter trial was conducted in the United States; patients with lung carcinoma received up to six cycles of cyclophosphamide, doxorubicin, and etoposide and were given G-CSF or placebo from day 4 to 17 of each cycle. The results showed a reduction in the median duration of severe neutropenia ($<0.5 \times 10^9$/L) from 6 to 3 days in the G-CSF arm and a 50% reduction of febrile neutropenia, hospitalizations, confirmed infections, and antibiotic use with G-CSF.[735] This study and other reports[736,737] have led the American Society of Clinical Oncology (ASCO) and the European Organization for Research and Treatment of Cancer (EORTC) to recommend the primary use of G-CSF in patients receiving chemotherapy protocols with an expected rate of neutropenia that exceeds 20%.[738,739] The use of G-CSF is recommended to support dose-dense or dose-intense chemotherapy regimes in adult carcinoma patients, but most studies do not show a significant effect on progression-free survival rates.[739] Patients in the placebo arm of the U.S. multicenter trial[735] who developed fever in the first treatment cycle were subsequently treated with G-CSF, and this reduced the duration of severe neutropenia from 6 to 3 days and neutropenic fever from 100% in cycle 1 to 23% in cycle 2. Thus the prophylactic use of G-CSF in chemotherapy-induced neutropenia is supported. However, the literature does not support the use of G-CSF or GM-CSF once afebrile[740] or febrile neutropenia has developed,[741,742] with the exception of one study.[743] Although days of neutropenia may be shortened, it has been difficult to show an effect on clinically significant end points such as shortened duration of hospitalization, which was seen in only one of the studies.[742]

GM-CSF. Recombinant hGM-CSF has been administered in phase I/II studies to several adult groups of patients with advanced malignant disease, both before and after chemotherapy.[744-746] Glycosylated GM-CSF produced in either mammalian (Chinese hamster ovary) cells or yeast, and *Escherichia coli*–derived nonglycosylated GM-CSF, have been evaluated with comparable results. A rapid, dose-related increase in polymorphonuclear neutrophils, monocytes, and eosinophils is observed in patients treated before chemotherapy. Neutrophils peak at around 20 to 30 × 10^9/L at doses of 4 to 32 mg/kg/day, and GM-CSF is well tolerated at doses up to this level. A capillary leak syndrome and venous thrombi are observed at higher doses (64 mg/kg/day).[744] Phase III randomized trials in patients with lymphoma or breast cancer have confirmed that GM-CSF given after chemotherapy is associated with shorter periods of neutropenia and higher leukocyte nadirs.[747-749] However, one of these studies included only the patients able to tolerate treatment and was not significant on an intention-to-treat basis. Furthermore, another study of GM-CSF after chemotherapy showed decreased neutropenia after the first treatment cycle only,[750] whereas two other studies showed no improvement in neutrophil counts.[751,752] In one of these studies[751] patients with small cell lung cancer were given chemotherapy and irradiation; compared with the placebo control, patients in the GM-CSF arm suffered more infections, toxic deaths, and longer hospital stays, and therefore the ASCO panel has cautioned against the use of CSFs in combined chemotherapy/irradiation regimens.[753,754]

Similar encouraging results have been obtained in children with solid tumors undergoing intensive chemotherapy.[755-757] Significantly shorter durations of severe neutropenia and thrombocytopenia were observed in a study of 25 children in whom yeast-derived GM-CSF was given at 60 to 1500 μg/m^2/day for 14 days after chemotherapy.[755]

Like G-CSF, GM-CSF also produced an increase in blood progenitor cells of both erythroid and myeloid lineages. Before chemotherapy, an eighteenfold increase in blood CFU-GM and an eightfold increase in BFU-E was noted; after chemotherapy, GM-CSF produced a much greater increase of progenitors (sixtyfold) when given during the recovery period.[755]

Erythropoietin. Anemia develops frequently in cancer patients, and correlates with poor performance status and decreased quality of life.[758] There is good evidence that rhEPO can increase the hemoglobin level in adults[759,760] and children[761] with anemia associated with cancer or its treatment. Three different EPO preparations are available: epoetin alfa (Epogen [Amgen], Procrit [Ortho Biotech], and Eprex [Ortho Biologicals, not sold in the United States]), epoetin beta (NeoRecormon [Hoffmann-LaRoche], sold in Europe), and darbopoetin alfa (Aranesp [Amgen], sold in the United States, Europe, Canada, and Australia). Differences in sialic acid carbohydrate composition of epoetin alfa and beta account for an increase in half-life from 8.5 hours (natural EPO) to 20 to 24 hours, whereas hyperglycosylation of darbopoetin results in a half-life of 49 hours.

Two 2003 randomized studies of patients with anemia and either head and neck cancer or breast cancer showed shorter survival times in the groups receiving EPO, raising concern that EPO can lead to disease progression.[762,763] Another study of advanced non–small cell lung cancer designed to compare EPO with placebo was stopped early when a safety analysis of 70 patients showed a significant survival advantage in the placebo group. Whether carcinoma cells express EPO receptors or not and whether they respond to EPO is controversial. Antibodies to EPO receptor lack specificity and do not distinguish cell surface from intracellular expression, and functional in vitro effects are frequently slight and found at supraphysiologic doses. However, EPO could still have adverse effects through indirect effects on endothelial cells or on angiogenesis.[764]

TPO. Because of TPO's potent in vitro activity and its role as the factor essential for terminal megakaryocytic differentiation, analogous to EPO for the erythroid lineage, clinical studies designed to assess its effect on platelet production have been reported. Both rhTPO and pegylated megakaryocyte growth and development factor (PEG-MGDF) are safe and show no organ toxicity, and in normal volunteers a single bolus of 3 μg/kg/day of PEG-MGDF doubles the blood platelet concentration by day 12, with a return to baseline by day 28.[765] A stimulatory effect on platelet production was observed when TPO or PEG-MGDF was administered after chemotherapy to more than 100 cancer patients, with a decrease in the time for platelet counts to return to normal and elevated platelet nadirs.[766-768] However, PEG-MGDF has caused the development of antibodies to TPO that resulted in severe thrombocytopenia (see below), and these cytokines have been withdrawn from clinical use. Small molecules, peptides, and a peptide-Fc antibody (AMG 531 "peptibody") that have no sequence homology with TPO but activate the receptor are under investigation.[769]

Bone Marrow Transplantation

GM-CSF and G-CSF have been evaluated in clinical autotransplantation trials.

GM-CSF. Patients with nonhematopoietic malignant diseases were treated with high-dose combination chemotherapy, autologous bone marrow transplantation, and rhGM-CSF given by continuous IV infusion for 14 days beginning 3 hours after bone marrow infusion. There was a dose-related increase in the neutrophil count at day 14.[770] Although not statistically significant, there was an improved neutrophil response in patients who had not received previous chemotherapy compared with those who had. Lower rates of morbidity and mortality were also noted among the patients who received the GM-CSF; bacteremia occurred in 16% of treated patients compared with 35% of evaluable controls. Comparable results were reported in a study of patients with lymphoid malignant diseases who received rhGM-CSF as a 2-hour infusion daily for 14 days following chemotherapy, radiotherapy, and autologous bone marrow transplantation.[771] Neutrophil and platelet counts recovered more rapidly; there were fewer days with fever; and the extent of hospitalization was reduced in comparison with an historical control group. In a pediatric study, nine patients received 5 to 10 μg/kg/day of GM-CSF after bone marrow transplantation. Neutrophil recovery was accelerated, although there was no difference in fever, infection, or length of hospitalization when compared with historical controls.[772] Similar results were obtained in a larger prospective double-blind randomized study of 40 patients.[773]

The response to GM-CSF after myelosuppression may be dependent on the infusion of sufficient progenitor cells. In an autotransplantation study of patients with acute lymphoblastic leukemia, bone marrows were purged with 4-hydroperoxycyclophosphamide and anti-T–cell or anti-B–cell lineage-specific antibodies before transplantation.[774] Thirty percent of the patients who received more than 64 μg/m^2/day of GM-CSF achieved an absolute neutrophil count of more than 1000/μL by day 21, whereas none of the nonresponders reached this level by day 27 following transplant. The responders required only one third as many platelet transfusions, and there was a trend toward fewer red cell transfusions, a higher myeloid : erythroid (M : E) ratio, and an earlier day of discharge in the responder group as well. Although bone marrow cell dose did not differ among the two groups, the number of CFU-GM progenitors infused per kilogram was significantly higher in the responders as compared with the nonresponders (17.5 [12 to 27] × 10^3/kg vs. 2 [0 to 7.2] × 10^3/kg). Although it is possible that the CFU-GM infusion, rather than the GM-CSF treatment, accounted for the more rapid recovery, all patients in the responder group showed a rapid decrease in ANC within 48 to 72 hours of discontinuing GM-CSF; this is consistent with a stimulatory effect on bone marrow. One can conclude that GM-CSF is effective in this context provided that sufficient progenitor cells are present.

G-CSF. Recombinant human G-CSF (rhG-CSF) was evaluated in patients with hematopoietic and nonhematopoietic malignant diseases after intensive chemotherapy and reinfusion of cryopreserved autologous bone marrow.[775] The rhG-CSF was given by continuous IV infusion from 24 hours after marrow infusion for a maximum of 28 days, beginning at 20 μg/kg/day and with the dose reduced after the neutrophil count persistently exceeded 1×10^9/L. The mean time to neutrophil recovery (>0.5×10^9/L) occurred by day 11, 9 days earlier than in historical controls. This led to significantly fewer days of parenteral antibiotic therapy, but there was no effect on red cell or platelet recovery. Although the rate of recovery from neutropenia was faster than that reported for rhGM-CSF, the latter studies were phase I dose escalation evaluations, and many patients did not receive an optimal dose of GM-CSF. In a prospective randomized study of 221 children receiving allogeneic or autologous bone marrow or peripheral blood stem cells, the patients treated with G-CSF showed more rapid neutrophil recovery, and this translated to clinical benefit in the bone marrow group (platelet transfusion independence and time to discharge).[776] A study compared G-CSF with GM-CSF in exactly the same bone marrow transplant protocol. Overall, total leukocyte recovery was slightly more rapid in the G-CSF group in comparison with the GM-CSF group. G-CSF administration resulted in two leukocyte peaks. The first at day 10 consisted of lymphocytes, while the second at day 14 consisted mostly of granulocytes; in contrast, GM-CSF produced a single peak at the end of the period of infusion. A major difference was observed with respect to neutrophil migration to an inflammatory site during CSF infusion after hematopoietic reconstitution.[777] Neutrophils did not migrate to skin chambers filled with autologous serum during GM-CSF treatment, a defect not encountered during the administration of G-CSF. There was, however, a similar reduction in the incidence of bacteremia with both GM-CSF and G-CSF (18% and 19%, respectively) in comparison with the historical controls (35%).

In conclusion, if neutrophil recovery is the goal following bone marrow transplantation, then G-CSF appears to be the factor of choice. It preserves neutrophil function and is well tolerated. The inability to hasten platelet recovery is still the major challenge.

Myelodysplasia

GM-CSF. Despite the theoretic risks of treating patients with myeloid stem cell clonal diseases with the CSFs, the factors have been evaluated in patients with refractory anemia (RA), RA with an excess of blasts (RAEB), RAEB in transformation (RAEBIT), and chronic myelomonocytic leukemia.[778-780] In an early study, GM-CSF was given by continuous infusion for 14 days, repeated after a 2-week rest period.[778] Five of the eight patients had received chemotherapy up to 4 weeks before the study. Doses of 30 to 500 μg/m^2 were used. Blood leukocytes rose 5-fold to 70-fold and neutrophils 5-fold to 373-fold, and an absolute increase in monocytes, eosinophils, and lymphocytes was also observed. Three of the eight patients also had a twofold to tenfold increase in platelet count and improvement in erythropoiesis, and two of the three became transfusion independent. Marrow cellularity increased, and there was a reduction in the proportion of blasts, although there was a transient dose-related increase in the absolute number of circulating blasts. No patient developed overt leukemia during the period of follow-up (≤32 weeks). There was no cytogenetic evidence for a reduction in abnormal clones; it is likely that stimulation of hematopoiesis affects both normal and abnormal cells. A dose-related increase in neutrophils, monocytes, eosinophils, and lymphocytes was also noted in a study of 11 patients with myelodysplasia. However, four patients who presented with more than 14% blasts in the bone marrow showed an increase in blasts after therapy, and an additional three patients showed an increase in blasts in the blood; five patients progressed to acute leukemia either during or within 4 weeks after treatment.[780] Unlike in the earlier report, none of these patients had received previous chemotherapy.

G-CSF. A number of patients have been treated with G-CSF.[781,782] Neutrophil responses were seen in five patients with myelodysplasia who received 50 to 1600 μg/m^2/day by intravenous infusion daily for 6 days. At the higher doses (400 μg/m^2/day) the increase was sustained and associated with an increase in bone marrow cellularity. No reticulocyte or platelet increases were observed, and no patient progressed to an acute phase. Similar results were reported in a study of 12 patients given G-CSF by daily subcutaneous injection, with dose escalation from 0.1 to 3 μg/kg/day over an 8-week period.[782] Although 10 of the 12 patients showed elevations in neutrophils (fivefold to fortyfold), an increase in reticulocytes occurred in five patients, with reduction in transfusion requirement in two patients. There was no response in other cell lineages and no conversion to acute leukemia.

Other Hematopoietic Growth Factors and Hematopoietic Growth Factor Combinations. Approximately 20% of patients show an increase in platelet counts during treatment with IL-3,[783,784] and a similar proportion show an increase in hematocrit or reduced transfusion requirement with EPO.[785] This erythroid response can be increased to about 40% if EPO is combined with either G-CSF or GM-CSF.[786,787]

In a review of this subject, Marsh and colleagues[788] concluded that although EPO can increase hemoglobin levels and reduce the need for transfusion, the cost-effectiveness of the approach is uncertain, as is safety with regard to the risk of progression. There is no compelling evidence for a survival benefit with the use of EPO or G-CSF in myelodysplastic syndrome (MDS).[788]

Aplastic Anemia

GM-CSF. Establishing a role for the CSFs in aplastic anemia has challenged investigators. Severe aplastic anemia is a heterogeneous disease that may result from either absent or defective stem cells, from microenvironmental defects, or from immunologically mediated suppression. The mortality rate is high, and therapeutic options are limited to bone marrow transplantation if an appropriate donor is available, or to immunosuppression (see Chapters 7 and 8). Although bone marrow transplantation can be curative, treatment with antithymocyte globulin (ATG) and cyclosporine is frequently effective but generally not curative. For these reasons rhGM-CSF has been evaluated in a number of phase I/II studies.

Administration of rhGM-CSF by bolus or continuous IV infusion for 7 or 14 days resulted in increased granulocytes, monocytes, and reticulocytes in six of eight cases.[779] In another small study, rhGM-CSF was given to cohorts of patients in escalating doses from 4 to 64 μg/kg/day by continuous IV infusion for 14 days. Although a dose-related effect was not observed, 10 of 11 evaluable patients had partial or complete responses in neutrophils, monocytes, and eosinophils, with increases in bone marrow cellularity. Importantly, the greatest increments occurred in patients with higher pretreatment neutrophil counts and more cellular marrows. Only 10% to 20% of patients show an increase in hemoglobin concentration and platelet count, and in all cases counts return to baseline after cessation of treatment.[778,789] In the first report of rhGM-CSF treatment in childhood, three quarters of the evaluable patients responded with a significant rise in neutrophil count during the 28-day induction period.[790] Although neutrophil counts returned to baseline after cessation of treatment in all the responders with severe aplastic anemia, one patient with moderate aplasia maintained a trilineage response when not receiving therapy for more than 1 year. One cannot extrapolate from such a small experience, but the data underscore the point that responses are more likely in less severely affected cases.

Thus in summary, it appears as though rhGM-CSF is palliative in aplastic anemia, with greater neutrophil responses evident in less severely affected patients. The most severely affected patients respond poorly.[791] No infections were observed during the study period in several reports, whereas infections were observed in others. Longer-term prospective comparative studies will be necessary to investigate morbidity rates.

G-CSF. Neutrophil responses have also been reported in a study of 20 children given 400 μg/m^2/day of G-CSF for 14 days.[792] Twelve patients responded by doubling their neutrophil counts, but other lineages were unaffected. In another pediatric study, high doses of G-CSF (400 to 2000 μg/m^2/day) induced neutrophil responses in 6 of 10 patients with very severe aplastic anemia.[793] Long-term treatment may be associated with multilineage responses when given alone[794] or in combination with cyclosporine.[795]

IL-3, IL-6, and EPO. Hematopoietic responses have been reported in a small phase I study of nine aplastic anemia patients given IL-3 in a dosage of 250 to 500 μg/m^2 (five of the nine doubled their neutrophil counts; four of the nine showed an increase in reticulocyte counts but no reduction in transfusion requirement; and one increased platelet counts from 1 to 31 × 10^9/L).[796] An increase in platelet count was reported in one of six patients entered in a phase I study of IL-6, although a dose-related decrease in neutrophils, monocytes, and lymphocytes was observed; and one of three patients given EPO showed a reduced transfusion requirement and/or an increase in hemoglobin levels (reviewed by Kojima[797]). Trilineage responses have been reported in a small number of refractory aplastic anemia patients treated with low doses of GM-CSF plus EPO[798] or G-CSF plus EPO.[799] The effects of EPO are unexpected because endrogenous levels are very high in aplastic anemia.

Human Immunodeficiency Virus Infection

GM-CSF. Human immunodeficiency virus (HIV) infection is associated with several hematologic abnormalities, including neutropenia, anemia, and thrombocytopenia. Anemia and neutropenia can be exacerbated by treatment with azidothymidine, and rhGM-CSF has been evaluated in an effort to enhance immunologic and hematopoietic function and improve tolerance to therapeutic agents. In the first report of the use of rhGM-CSF in humans, cohorts of acquired immunodeficiency syndrome (AIDS) patients were treated with increasing doses of factor given by 14-day continuous IV infusion.[800] This resulted in a rapid, dose-related increase in neutrophils, bands, and eosinophils, with a slight increase in monocytes. A follow-up study with subcutaneous administration showed that these effects could be sustained for up to 6 months without evidence of tachyphylaxis.[800]

A concern with the use of GM-CSF in AIDS is possible enhancement of HIV replication. In one study of azidothymidine given on an alternate-week schedule with GM-CSF, some patients showed increased viral p24 levels during therapy with GM-CSF. There is evidence, however, that GM-CSF may in fact augment azidothymidine levels in monocytes, which suggests that the combination of azidothymidine and GM-CSF might be advantageous.[801] This is not the case with newer nucleoside analogues such as dideoxycytidine and dideoxyinosine (reviewed by Mueller[802]). Two clinical studies have documented an increase in HIV p24 antigen while patients were receiving GM-CSF,[803,747] and therefore GM-CSF has been replaced by G-CSF for the treatment of neutropenia.

G-CSF. In a pilot study at the National Institutes of Health (NIH), G-CSF was evaluated in 19 pediatric AIDS patients who developed neutropenia while receiving azidothymidine. The neutrophil count increased from a median of 1 × 109/L to 2.9 × 109/L at doses of 1 to 20 μg/kg/day, and in 17 of the 19 patients, continued azidothymidine was well tolerated.[804] Of note was the development of thrombocytopenia in some patients; two patients developed G-CSF–dependent disseminated intravascular coagulation, and one patient developed an increase in myeloblasts that disappeared after the G-CSF was stopped.[802]

Erythropoietin. EPO has been used in 12 anemic pediatric patients to determine if tolerance to azidothymidine could be improved.[802] EPO was well tolerated, and at doses from 150 to 400 U/kg subcutaneously or intravenously 3 times a week all patients could be maintained on azidothymidine, with marked reduction (four patients) or moderate reduction (four patients) in transfusion requirement.

Inherited Bone Marrow Failure Syndromes

The use of HGFs in the treatment of inherited bone marrow failure syndromes has been reviewed in detail.[805,806]

Fanconi Anemia. GM-CSF has been studied in seven patients with Fanconi anemia (FA),[807] and trials of IL-3 and G-CSF[805] show that all three HGFs can improve the neutrophil count in most pancytopenic patients but that platelet and hemoglobin levels are unaffected.

Diamond-Blackfan Anemia. Although there is no evidence that Diamond-Blackfan anemia (DBA) is due to deficiency of EPO,[808] IL-3, or GM-CSF,[809] or to an abnormality of KIT or its ligand SCF,[810,811] it is possible that pharmacologic doses of these factors might stimulate erythropoiesis. Niemeyer and colleagues[812] observed no reticulocyte or hemoglobin responses in nine patients treated with rhEpo doses as high as 2000 U/kg/day. In contrast, three of six patients treated with IL-3 (60 to 125 μg/m^2/day subcutaneously for 4 to 6 weeks) had reticulocyte increases, and two of the responders remained transfusion independent for 1.5 to 2 years when not receiving therapy.[813] Another IL-3 study[814] showed 4 responders out of 18 patients treated with 0.5 to 10 μg/kg subcutaneously. Two responders developed deep vein thromboses, necessitating discontinuation of treatment, and the other two patients sustained their responses, one on maintenance IL-3 for 31 months and one without treatment for 12 months after 30 months of therapy. In another study of 13 patients, no responses were observed.[815] Thus 6 patients have had significant erythroid responses to IL-3 out of a total of 37 patients (14%), a rate similar to that reported by the European working group for DBA (3 of 25 patients).[816]

Amegakaryocytic Thrombocytopenia. Amegakaryocytic thrombocytopenia (AMT) is a rare disease that presents in infancy or early childhood with thrombocytopenia, frequent anemia, and progression to pancytopenia. Bone marrow megakaryocytes are absent or extremely scarce, and the disease results from mutations in the TPO receptor MPL. A phase I/II IL-3 dose escalation study without or with sequential GM-CSF in five children with AMT showed that IL-3 (but not IL-3/GM-CSF) induced platelet responses in two patients and improvement in bruising, bleeding, and transfusion requirement in the other three patients.[720] The two platelet responders became unresponsive after several months of IL-3 maintenance (125 to 250 μg/m^2/day), and another patient became platelet transfusion independent after 4 months of IL-3 and had a trilineage response sustained for almost 2 years.

Severe Congenital Neutropenia. Severe congenital neutropenia (SCN) (see also Chapter 8) is a disorder of myelopoiesis characterized by impaired neutrophil differentiation and absolute neutrophil counts less than 200/μL. In contrast, monocytes and eosinophils are normal or increased. The bone marrow shows maturation arrest at the promyelocyte stage, and these cells are often atypical, with abnormal nuclei and vacuolated cytoplasm. The pathophysiology is uncertain, despite the identification of mutations in neutrophil elastase (ELA2) and, more recently, HAX1 in recessively inherited disease.[817] Serum from these patients contains normal or elevated levels of G-CSF, as determined by Western blot testing[818] and bioassay.[819] Other investigations showed mutations in the C-terminal “differentiation” domain of the G-CSFR in two patients.[419]

The responses of these patients to exogenous G-CSF and GM-CSF are therefore of great interest. One study has compared the effects of GM-CSF and G-CSF in a small number of patients, and G-CSF alone was evaluated in other studies.[820-822] In these investigations, *G-CSF produced a remarkable increase in neutrophils in all patients*. The dose necessary to maintain a neutrophil count of more than 1000/μL varied, and ranged from 3 to 15 μg/kg/day. The monocyte count was also increased. In contrast, rhGM-CSF produced an increase in neutrophils in only one patient, and the others showed an increase in eosinophils and monocytes. Although the period of the study was short, no new episodes of severe bacterial infection occurred during either GM-CSF or G-CSF treatment; this contrasts with the recurrent bacterial and fungal infections that occurred before treatment. A multicenter phase III study of G-CSF in 120 patients with severe chronic neutropenic disorders, including severe congenital neutropenia, Shwachman-Diamond syndrome, and myelokathexis showed complete responses in 108 patients (ANC >1.5 × 10^9/L), partial responses in 4 patients, and failure of response in 8 patients.[823] Although the majority of patients responded with an ANC equal to or more than 1 × 10^9/L at doses in the range of 3 to 20 μg/kg/day, about 25% of patients needed 20 to 100 μg/kg/day or more.[806]

Somatic mutations of a single allele of the G-CSFR that result in loss of the C-terminal “differentiation” domain of the receptor were described in several SCN patients, and shown to act as a dominant negative in transduced cells.[824,825] These patients may go on to develop MDS and or acute myeloblastic leukemia (AML).[419] Data from the Severe Chronic Neutropenia International Registry[826] regarding 506 patients with severe congenital neutropenia, cyclic neutropenia, and idiopathic neutropenia who were treated during phase I to III clinical G-CSF trials showed that 23 of 249 patients with severe chronic neutropenia (SCN)/Schwachman-Diamond syndrome (neutropenia and pancreatic insufficiency) developed MDS/AML, in comparison with none of the 97 patients with cyclic neutropenia or the 160 patients with idiopathic neutropenia. The observation that SCN patients receiving G-CSF develop MDS/AML but cyclic or idiopathic neutropenia patients do not is consistent with reports of AML in SCN before the introduction of G-CSF treatment,[827,828] and show that SCN is a preleukemic disease. Additional cytogenetic changes (translocations and monosomy 7) and oncogene (RAS) mutations are common in the patients that go on to develop MDS/AML.[829] The G-CSFR mutation is present in myeloid cells only and was not present in first-degree relatives of affected patients, including a sibling with SCN,[830] demonstrating that the mutation is acquired. Interestingly, detailed study to identify the risks for leukemic transformation show increased risk over time (2.9% per year after 6 years; 8% per year after 12 years; cumulative incidence, 21% after 10 years). Importantly, the risk of MDS/AML correlates with the dose of G-CSF; 40% of the poor responders developed MDS/AML (G-CSF dose higher than the median of 8 μg/kg/day and ANC less than the median of 2188 cells/μL at 6 to 8 months), compared with only 11% of the good responders.[831] Similar results were reported by the French Severe Chronic Neutropenia study group.[832]

In summary, treatment with recombinant G-CSF has had a major positive impact on the lives of the majority of these patients. This continued treatment has increased the risk of emergence of leukemic clones in this preleukemic disease, and patients need to be monitored regularly for their acquisition. Patients who respond poorly to G-CSF should be considered earlier for stem cell transplantation.

Cyclic Neutropenia. Cyclic neutropenia (see also Chapter 8) is a rare HSC disease due to mutations in neutrophil elastase (ELANE). It is characterized by regular 21-day cyclic fluctuations in numbers of neutrophils, monocytes, eosinophils, lymphocytes, platelets, and reticulocytes. Patients typically have recurrent episodes of fever, malaise, mucosal ulceration, and, occasionally, life-threatening infection during periods of neutropenia. Six patients were treated with IV or subcutaneous rhG-CSF for 3 to 15 months at doses ranging from 3 to 10 μg/kg/day.[833] The median neutrophil count increased from 0.7 × 10^9/L to 9.8 × 10^9/L. In five of the patients, cycling of blood counts continued, but the length of cycles decreased from 21 to 14 days. The number of days of severe neutropenia (<200/μL) was reduced from a mean of 12.7 per month to less than 1 per month, and, importantly, the nadir counts increased; neutrophil turnover increased almost fourfold; and migration to a skin window was normal. Average counts of other cells did not increase. One patient with disease of adult onset had a qualitatively different response, with an increase in neutrophils and disappearance of the cyclic fluctuations in count. Therapy reduced the frequency of oropharyngeal inflammation, fever, and infection, demonstrating that treatment with rhG-CSF is effective management for such patients. These results have been confirmed in other studies, and treatment is well tolerated.[834-836] In one study, GM-CSF was not effective in two patients but eliminated severe neutropenia when given in a low dose (0.3 μg/kg/day).[837-839]

Anemia of Chronic Renal Failure

Erythropoietin. Anemia is a major complication of end-stage renal failure and is due primarily to a reduction in erythropoietin production. Other mechanisms that may be involved are shortened red cell survival, iron deficiency, hypersplenism, possible circulating inhibitors of erythropoiesis, and aluminum-induced microcytosis. Several phase I, II, and III studies have documented that rhEpo can induce a dose-dependent increase in effective erythropoiesis.[840-842]

In a phase III study, patients received 150 or 300 U of rhEpo 3 times per week following hemodialysis, and reached a target hematocrit of 35% by 8 to 12 weeks.[841,842] Most patients required 50 to 125 U/kg intravenously 3 times per week following dialysis to maintain a hematocrit of approximately 35%. The increase in erythropoiesis needed to normalize the hemoglobin level requires mobilization of a considerable amount of iron; patients who improve, particularly those who improve rapidly, can develop absolute or relative iron deficiency. If iron is not given, the response to rhEpo becomes blunted; the standard corrective measure is IV administration of iron dextran or oral iron supplementation. Regular measurements of ferritin and transferrin saturation are necessary to ensure that iron stores are adequate.

Erythropoietin has been well tolerated and has resulted in elimination of transfusion dependency. Hypertension, occasionally with encephalopathy, has been observed, particularly with rapid rises in hematocrit that lead to an increase in peripheral vascular resistance; induction with doses of not more than 150 U/kg is recommended to produce a gradual increase in hemoglobin levels. Some patients require either the initiation of antihypertensive medication or an adjustment of dosage. A marked increase in pure red cell aplasia occurred from 1998 to 2004 because of the development of anti-EPO antibodies,[843-845] with reports of approximately 250 suspected or proven cases. The complication, characterized by reticulocytopenia, absence of erythroid precursors, and severe anemia, has occurred mostly in adults (a few children are included) with renal disease who were treated with Eprex outside the United States, but cases have been reported in the United States as well. Differences in EPO glycosylation status and drug formulation, processing, storage, and route of administration appear to affect the immunogenicity of EPO. The estimated exposure-adjusted incidence per 100,000 patient-years was 18 cases for Eprex without serum albumin (epoetin alfa, Ortho Biotech), 6 for Eprex with serum albumin, 1 for Neorecormon (epoetin beta), and 0.2 for Epogen (epoetin alfa).[845] Changes in drug formulation and drug monitoring programs have led to an 80% reduction in the incidence of pure red cell aplasia, and EPO should not be withheld for this reason.

The effect of rhEpo in most studies appears to be restricted to the erythroid lineage. However, data from a phase III study of 303 patients show a significant increase in mean platelet count (224 × 10^9/L to 241 × 10^9/L at 6 months), which is not biologically meaningful. There is also a slight increase in blood urea nitrogen, creatinine, and serum potassium levels. The bone marrow progenitors from patients with end-stage renal failure were studied before and 2 weeks after rhEpo treatment. The concentration of BFU-E, CFU-E, and CFU-Meg increased after therapy. Surprisingly, an increment in CFU-GM also occurred, and the number of progenitors of all classes in cell cycle almost doubled.[846]

Subjective improvement in appetite, energy, sleep pattern, and libido are also noted. A Canadian double-blind placebo-controlled study of rhEpo treatment has provided objective evidence of benefit.

Extending this treatment to patients who do not yet require dialysis has met with similar success.[847] An issue that has yet to be resolved is the financial cost; rhEpo is not inexpensive, and the National Kidney Foundation in the United States has issued guidelines for the use of rhEpo in which all patients with a hematocrit of less than 30% will be eligible. rhEpo is more effective when administered by the subcutaneous route; this route is more convenient for patients and also allows for a dose reduction.[848,849] In predialysis patients, 100 U/kg given subcutaneously provided a response similar to that when 150 U/kg was given intravenously.[848] There is evidence that the bioavailability of subcutaneous EPO is seven times greater than that of the intravenously administered drug, and a large controlled study showed that the mean EPO dose given to maintain a stable hematocrit was 32% lower when EPO was given by the subcutaneous route rather than the IV route.[850]

Similar results have been obtained in several rhEpo studies in children (reviewed by Müller-Wiefel[851]). Anemia was corrected by 3 to 4 months in 24 children with preterminal chronic renal failure treated with rhEpo and iron, which was adjusted by careful monitoring of iron status. Hypertension is the most common side effect.[852-855] Interestingly, although the growth failure of children with terminal chronic renal failure is unaffected by rhEpo treatment, the mean growth velocity in 22 children with preterminal chronic renal failure increased from −2.29 to −0.56 within the first 6 months of treatment.[851] Other possible benefits include reports of delay in progression of renal dysfunction in children with preterminal chronic renal failure and of improvement in cognitive function.

Other Indications for Recombinant Erythropoietin Therapy

Several small clinical trials have evaluated the use of rhEpo in the anemia of prematurity.[856-862] These studies have been reviewed by Mentzer and Shannon,[863] and although study differences in patient population, transfusion criteria, rhEpo dose, and iron therapy make comparisons difficult, rhEpo treatment has been shown to be safe and to stimulate a reticulocyte response. An effect on hematocrit was observed only in the studies in which doses of more than 500 U/kg/week were used,[856,858,860,861] and there appears to be a modest effect on transfusion requirement. Increasing the dose from 750 U/kg/week to 1500 U/kg/week was not supported by a large European study of 184 very–low-birth-weight infants.[864]

Preliminary data suggest that rhEpo may be useful in the treatment of patients with the anemia of chronic disease associated with rheumatoid arthritis[865] and the anemia that complicates azidothymidine treatment in patients with AIDS (see discussion above).

In simian studies, hemoglobin F levels can be increased by administration of erythropoietin.[866] If similar changes occur in humans, erythropoietin may have a role in the management of sickle cell disease and thalassemia. Several small studies in sickle cell disease have shown that an F reticulocytosis can occur in some patients, whereas other patients show an increase in hemoglobin without a sustained F-reticulocyte response, a finding that is of some concern because blood viscosity might be increased.[867] There are also data to suggest that hydroxyurea in combination with EPO can augment the F-reticulocyte response, although the contribution of EPO is still uncertain.[868,869] In patients with transfusion-dependent or untransfused thalassemia, variable responses to EPO alone have also been reported,[870-873] with some patients showing an increase in hemoglobin and F cells. The only report to show a consistent increase in fetal hemoglobin was a study of 10 untransfused thalassemic patients who received rhEpo (400 to 800 U/kg 3 times weekly), as well as iron and hydroxyurea 4 days per week. Hemoglobin counts increased significantly in 8 of the 10 patients, with concomitant increases in fetal hemoglobin 5% to 20% above baseline.[873]

Finally, erythropoietin can be used to increase the number of units of blood that can be obtained preoperatively in the context of autologous blood donation.[874]

Immune Thrombocytopenic Purpura. TPO Mimetics. Two small molecules that can activate the TPO receptor (MPL) are under intense study and have been approved by the Food and Drug Administration (FDA) for immune thrombocytopenic purpura (ITP). Romiplostim has four peptides linked to an IgG Fc fragment that binds to the TPO receptor in the same way as TPO; it is administered by weekly subcutaneous injection. Eltrombopag is an orally administered nonpeptide drug that activates the TPO receptor by binding to its transmembrane domain. In normal individuals both agents produce a dose-dependent rise in platelet count beginning on day 5 and peaking at around 2 weeks. There is evidence that ITP is not only due to increased platelet destruction but that immune-mediated megakaryocyte damage and decreased platelet production are also important,[875] providing a compelling rationale for the use of TPO mimetics in ITP.[876-878] In an open-label study of nonsplenectomized ITP patients who had failed standard therapy, 234 adult patients were randomized to receive romiplostim or standard care. Romiplostim was associated with better outcomes with respect to sustained platelet response, less bleeding, fewer transfusions, a decreased requirement for other treatments, and improved quality of life.[879] Two smaller placebo-controlled pediatric studies showed similar results.[880,881] In the EXTEND (Eltrombopag eXTENed Dosing Study), safety, efficacy, and tolerability were studied in 299 patients with ITP of more than 6 months' duration for up to 3 years.[882] Bleeding symptoms affected 56% of patients at baseline and decreased to 20% and 11% at 2 and 3 years, respectively. Platelet counts were maintained at more than 50,000/μL and 2 times baseline in at least two thirds of the cumulative study weeks for both splenectomized and nonsplenectomized subjects. Furthermore, 65% of the 69 patients who attempted to decrease concomitant treatment were able to sustain a reduction or permanently stop one or more of these therapies.

Stem Cell and Progenitor Cell Mobilization

The effect of G-CSF on progenitor cells is interesting. After melphalan and G-CSF, the absolute number of *circulating* progenitor cells of the granulocyte-macrophage, erythroid, mixed, and megakaryocyte lineages show a dose-related increase up to 100-fold after 4 days of treatment with rhG-CSF,[883] confirming earlier animal studies.[884,885] The relative proportion of the early and late granulocyte progenitors and of early progenitors of different lineages remains unchanged; however, CFU-E, normally undetectable in the blood, are markedly increased. The mechanism for the increase in all progenitors in the blood is unclear; G-CSF has been shown to affect immature blast colony-forming cells, and it is possible that stem cells are stimulated in vivo to produce increased progenitors of all classes; alternatively, G-CSF may indirectly stimulate progenitors by induction of HGF production or by release into the circulation of bone marrow progenitor cells.

These early studies set the stage for attempts at high-dose chemotherapy followed by mobilized blood progenitor cell rescue in a number of chemosensitive tumors such as lymphoma, breast cancer, and multiple myeloma. Time to engraftment is critically related to the number of CD34+ cells infused, and a number of studies indicate that a dose of 5 × 10^6 CD34+ cells per kilogram or higher results in prompt neutrophil and platelet engraftment.[886-889] G-CSF is the usual HGF used to mobilize progenitors, and multiple apheresis procedures (four or more) are commonly required to achieve this dose of CD34+ cells. Strategies to increase the yield and thereby reduce the number of apheresis procedures include the combination of G-CSF with chemotherapy or SCF.[889-892] Two studies suggest that SCF in combination with G-CSF can decrease the number of required apheresis procedures[889,893]; this might be expected to have several advantages, including reduction of apheresis-associated morbidity, less delay in administration of chemotherapy, and decreased cost. Another strategy is to combine G-CSF with plerixafor,[894] an inhibitor of the interaction between stem cell CXCR4 and stromal-derived SDF-1, or to use plerixafor alone.[895]

Toxicity of Treatment with Colony-Stimulating Factors

The CSFs tested in all these clinical trials have in general been well tolerated. Both GM-CSF and G-CSF induce a transient leukopenia in the first 30 minutes after administration by IV bolus. GM-CSF rapidly induces surface expression of the leukocyte adhesion protein CD11b (MO1) in vitro, and this is accompanied by an increase in neutrophil aggregation.[715] CD11a (LFA-1) and CD11c (gp150/95), two other members of this family of cell surface adhesion glycoproteins that have distinct alpha chains but share a common beta chain (CD18) with CD11b, are unaffected by GM-CSF. These results have been corroborated by in vivo studies of sarcoma patients who received 32 or 64 µg/kg/day of GM-CSF. A marked increase of CD11b was noted that was evident by 30 minutes and persisted for 12 to 24 hours after treatment.[896] Radionuclide-labeled leukocytes are sequestered in the lungs after GM-CSF treatment,[734] probably because of the aggregability and adhesiveness induced by increased CD11b expression. Breathlessness and hypoxia have been observed in some patients, particularly after short-duration IV administration. CD11b is not modulated by G-CSF, and the reason for the transient leukopenia following treatment with G-CSF is at present unclear.

Both GM-CSF and G-CSF have been associated with bone pain coincident with or shortly after administration. Occasional increases in leukocyte alkaline phosphatase and/or lactate dehydrogenase have been noted. In contrast, GM-CSF has induced flulike symptoms, including fever, flushing, malaise, myalgia, arthralgia, anorexia, and headache. Mild elevations of transaminase levels and rash are also reported. These effects are usually mild, are alleviated by antipyretics, and disappear with continued administration. More serious GM-CSF toxicity has been observed at higher dose levels (>32 µg/kg/day given intravenously or >15 µg/kg/day given subcutaneously). These include a capillary leak syndrome, with weight gain due to fluid retention, manifested as pericardial or pleural effusions, ascites, and/or edema.[744,770] Phlebitis was noted in initial studies when the GM-CSF was infused into small veins; large-vessel thrombosis has occurred with infusion of high doses into central veins.[744]

Antibodies to Recombinant Factors

rhGM-CSF that is produced in mammalian cells (Chinese hamster ovary [CHO] cells) is variably glycosylated on both O-linked and N-linked sites. Production in *E. coli* results in nonglycosylated GM-CSF, and the yeast product is glycosylated at N-linked sites. All three products appear to be equally efficacious, but antibodies have been reported in 4 of 13 patients given the product derived from yeast in phase I/II studies.[897] The IgG antibodies developed by 7 days after the start of the infusion in all four patients, three of whom had received a bolus test dose; the antibodies were nonneutralizing as judged by bone marrow colony-forming assay, and they were directed at sites on the protein backbone of the GM-CSF molecule that are normally protected by O-linked glycosylation but that are exposed in the products derived from yeast or *E. coli*. Transient antibodies to TPO have been reported in one cancer patient.[898] However, the development of antibodies in both patients and volunteers given PEG-MGDF led to termination of further clinical development of this TPO formulation, because transient decreases in platelet count were noted.[899,900,765,901] Antibodies to erythropoietin can also develop in patients with the anemia of chronic renal failure who are receiving treatment with erythropoietin.[902] Some formulations of EPO were associated with an antibody to EPO that resulted in pure red cell aplasia; this complication is discussed more fully above in the section on the use of EPO in renal failure.

No dose-limiting toxicity has been observed with G-CSF. However, one case of pathogenic neutrophil infiltration (acute febrile neutrophilic dermatosis, or Sweet syndrome) has been reported.[903] One patient with severe congenital neutropenia developed cutaneous necrotizing vasculitis (leukoclastic vasculitis) while receiving G-CSF treatment.[819,821] As noted above, there is also concern that G-CSF will induce or accelerate the development of acute myeloblastic leukemia or myelodysplasia with monosomy 7 in aplastic anemia and SCN; such a development is perhaps more likely in patients with G-CSF receptor mutations that can transduce a proliferative signal but not a differentiation signal.

As noted above, erythropoietin treatment has been associated with an increased risk of thromboembolic complications in adults, particularly when target hemoglobin concentrations were in the normal range, with a possible adverse effect on breast cancer progression.[763,904] Two randomized studies in which the targeted hemoglobin level was either in the normal range (>13.5 g/dL) or subnormal range (10.5 to 11.5 g/dL) showed an increased risk of adverse cardiovascular effects for the normal hemoglobin groups.[905,906] A 2006 update of a Cochrane review of 57 trials including more than 9000 patients showed strong evidence that epoetin and darbepoetin increased the risk of thromboembolic complications compared with controls (relative response [RR] 1.67; 95% confidence interval 1.35 to 2.06).[907] There are no comparable large studies in children. As a result of these and other studies, the FDA has recommended the lowest dose possible to increase the hemoglobin to a level that avoids transfusion, not to exceed 12 g/dL or a rise of more than 1g in any 2-week period (see).

TPO mimetics have been associated most frequently with nausea and vomiting (5% to 7% of patients), and serious adverse events include thromboembolism (2%) and elevations in alanine transaminase and bilirubin (4% to 7%).[876,907a] Studies in rats showed an increase in bone marrow reticulin fibrosis with high doses of romiplostim, and this has raised concern in clinical studies. In general, fibrosis appears to be mild and reversible with cessation of the drug.[908]

CONCLUSION

Advances in molecular and cell biology have led to an unraveling of some of the most challenging and confusing aspects of the study of hematopoiesis. Therapeutic benefits have emerged from these discoveries. The field of hematopoiesis, once a jumble of unknown factors and activities, has come of age and is providing direct benefits to countless patients.

CHAPTER 2

The Neonatal Erythrocyte and Its Disorders

Patrick G. Gallagher

CHAPTER OUTLINE

INTRODUCTION
THE NEONATAL ERYTHROCYTE
NORMAL HEMATOLOGIC VALUES
NEONATAL ANEMIA
HEMORRHAGE IN THE FETUS AND NEWBORN
- Prenatal Hemorrhage
- Intrapartum Hemorrhage
- Postpartum Hemorrhage
- Clinical Manifestations of Fetal and Neonatal Hemorrhage

HEMOLYSIS IN THE FETUS AND NEWBORN
- Extrinsic Hemolysis
- Intrinsic Hemolysis

DECREASED ERYTHROCYTE PRODUCTION
PHYSIOLOGIC ANEMIA AND ANEMIA OF PREMATURITY
APPROACH TO THE ANEMIC INFANT
POLYCYTHEMIA HYPERVISCOSITY SYNDROME

INTRODUCTION

At no other time in the life of a patient is the physician confronted with as many diagnostic considerations in the interpretation of apparent disturbances of the erythrocyte as during the neonatal period. Neonatal erythrocytes are fundamentally different from those of older children and adults, varying in size, shape, globin composition, oxygen transport, membrane characteristics, cellular metabolism, and life span.[1] Because of these differences, evaluation of a neonate with a suspected erythrocyte disorder mandates a thorough understanding of developmental erythropoiesis (reviewed in Chapter 1), appreciation of the differences between neonatal and adult red blood cells (RBCs), understanding of perinatal conditions influencing the fetus and newborn, and knowledge of inherited and acquired disorders of the erythrocyte that manifest in the neonate.

THE NEONATAL ERYTHROCYTE

Erythrocyte Size

Early in embryogenesis, the size and volume of erythrocytes are significantly greater than that of neonatal and adult erythrocytes, with the mean corpuscular volume (MCV) ranging from 150 to 180 fl and cellular diameter ranging from 20 to 25 μ. Erythrocyte size and volume decrease throughout gestation to values of MCV between 108 to 118 fl and diameter between 8 to 10 μ at term (Table 2-1). After birth,[2] erythrocytes continue to decrease in size and volume, with values similar to those of adults by 1 year of age.

Erythrocyte Shape and Deformability

Marked variability exists in the shape of fetal and neonatal erythrocytes. Irregularly shaped erythrocytes are found in larger numbers on the peripheral blood smears of hematologically normal term neonates than on those of adults (Fig. 2-1). Acanthocytes, target cells, and immature erythroid cells with various membrane projections are frequently seen.[3] These variations have been attributed to poor or absent splenic function in neonates. Decreased splenic function is also associated with membrane surface "pits," the site of formation of endocytic vacuoles, attributed to immaturity of the neonatal macrophage pitting process.[4] Nearly half of erythrocytes from preterm infants and a quarter of erythrocytes from term infants have surface pits compared with approximately 2% of normal adult erythrocytes.[5] Erythrocyte deformability is determined primarily by three factors: the surface/volume relationship of the cell, cytoplasmic viscosity, and intrinsic membrane rigidity. Cellular deformability influences several processes, including whole blood viscosity, which in turn affects peripheral vascular resistance and cardiac workload, flow in the peripheral circulation, and the life span of the erythrocyte. As erythrocytes age, neonatal cells lose more volume, have a higher mean corpuscular hemoglobin concentration, and become less

deformable than adult RBCs, with decreased deformability leading to increased splenic sequestration. Together these properties lead to accelerated membrane loss and decreased erythrocyte life span.[6,7]

Membrane Differences

Fetal and neonatal erythrocyte membranes demonstrate additional characteristics that differ from those of adult cells (Box 2-1). Fetal and neonatal erythrocytes contain more phospholipid and cholesterol per cell,[8] resulting in a larger surface to volume ratio and rendering them slightly more osmotically resistant.[9] This observation has practical clinical importance, because when osmotic fragility testing is used in a neonate to diagnose hereditary spherocytosis (HS), a normative neonatal osmotic fragility curve should be used rather than the standard adult curve. The surface charge of neonatal erythrocytes is

Box 2-1 Some Structural Characteristics of Fetal Erythrocytes Compared with Adult Erythrocytes

Membrane Structure and Function

- Less osmotically fragile
- Differences in surface antigen expression
  - A and B antigens diminished
  - Lewis system diminished
  - I antigen very diminished (or absent): i antigen present
- Possible decreased structural stability as a result of increased levels of unbound 2,3-diphosphoglycerate
- Membranes less deformable
- Red cells of different shapes with a greater predominance of stomatocytes than adult cells
- Increased variability of the smear with multiple morphologic changes
- Red cell membrane pits (as a result of decreased splenic function)

From Wolfe LC: Neonatal anemia. In Handin RI, Lux SE, Stossel TP, editors. Blood: principles and practice of hematology, *Philadelphia, 1995, JB Lippincott, p. 2107.*

more negative than that of adult cells because of a higher sialic acid content.[10] This increased negative charge contributes to the decreased erythrocyte sedimentation rate observed in newborns.[11] Neonatal erythrocytes contain increased amounts of total and membrane-associated myosin compared with adult cells.[12] Membrane acetylcholinesterase is decreased.[13] Permeability to monovalent cations is increased, and less sodium-potassium adenosine triphosphatase activity is required for monovalent cation removal.

The expression of various antigens and surface receptors vary between neonatal and adult erythrocytes. The major RBC antigens—Rh, MN, Kell, and Duffy—are well developed in early intrauterine life. Other membrane-associated antigens—Lutheran, ABO, I, and XgA—are incompletely developed at birth. Other antigens, such as the Lewis antigen, are absent at birth. Neonatal erythrocytes express higher levels of several membrane-associated proteins, such as the insulin and insulinlike growth factor receptors, while expressing fewer digoxin receptors than adult erythrocytes.[14]

The i antigen is a commonly used marker of fetal erythropoiesis. Differences in the glycans attached to the external surface of band 3, the anion exchanger, account for this developmental marker.[15] In fetal cells the chain is arranged in an unbranched, linear fashion (i antigen with i reactivity), whereas the chain is arranged in a branched manner in adult cells (I antigen with I reactivity).[16] The i antigen predominates in fetal and neonatal cells, gradually decreasing in a reciprocal relationship with the I antigen, which gradually increases, until approximately 18 months of age. Adult erythrocytes express minimal to no i antigen.

Globin Composition and Oxygen Transport

The synthesis and composition of embryonic, fetal, and neonatal globins are described in Chapter 19. Depending on gestational age, approximately 70% to 90% of the hemoglobin in the erythrocyte of the fetus and neonate is fetal hemoglobin (HbF). HbF is more soluble in strong phosphate buffers and is resistant to acid denaturation.[17] This latter characteristic is the biochemical basis of the Kleihauer-Betke test (discussed later).

An important functional difference between HbF and adult hemoglobin (HbA) results from the ability of HbA, but not HbF, to interact with phosphorylated compounds, particularly adenosine triphosphate (ATP) and 2,3-diphosphoglycerate (2,3-DPG). The interaction of HbA with 2,3-DPG leads to a marked decrease in oxygen affinity.[18] In contrast, HbF has no or minimal interaction with these organic phosphates, leading to a relatively higher oxygen affinity of fetal blood, with a leftward shift of the oxygen dissociation curve (Table 2-2; Fig. 2-2) compared with adult blood. In utero, this characteristic is of significant benefit to the fetus because it facilitates placental oxygen exchange from maternal blood to fetal erythrocytes.

Cellular Metabolism

Fetal and neonatal erythrocytes have a number of metabolic differences compared with adult cells (Box 2-2).[19]

§P_{50} of adult hemoglobin.

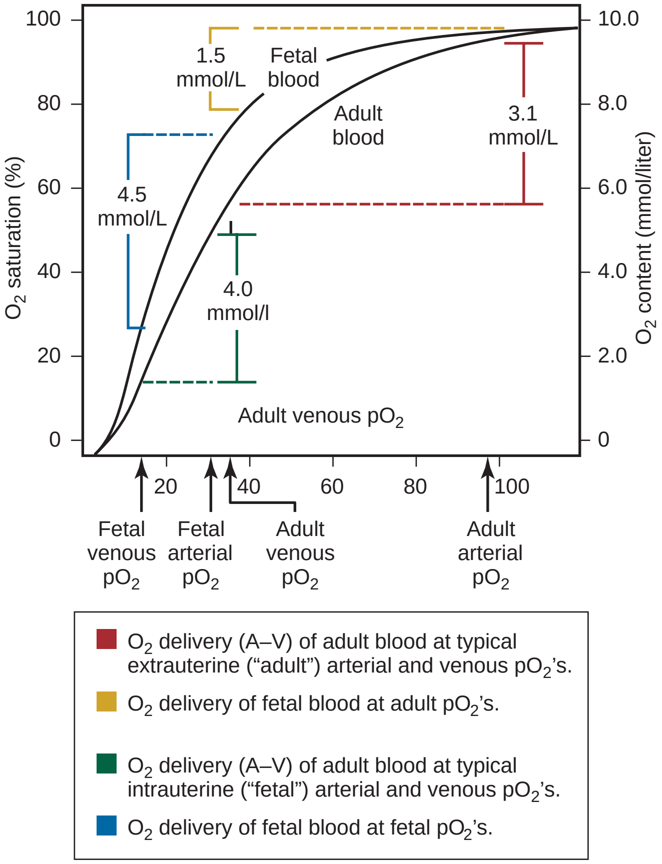

Figure 2-2 Difference in the hemoglobin–oxygen (O_2) dissociation curve between newborns and adults. The left shift of the newborn curve enhances the amount of O_2 that can be delivered at lower O_2 tensions. For example, comparing the difference in O_2 content of blood at fetal arterial and venous (A-V) partial pressure of oxygen (pO_2) values, fetal blood delivers 4.9 mmol/L, whereas adult blood delivers only 4 mmol/L. In contrast, at typical adult arterial and venous pO_2 values, adult blood delivers more O_2 (3.1 mmol/L) compared with fetal blood (1.5 mmol/L). *(From Stockman JA: Fetal hematology. Box 2-2 Metabolic Characteristics of Neonatal Erythrocytes

CARBOHYDRATE METABOLISM

Glucose consumption increased
Galactose more completely used as substrate under normal circumstances and for methemoglobin reduction*
Decreased activity of sorbitol pathway*
Decreased triokinase activity*

GLYCOLYTIC ENZYMES

Increased activity of hexokinase, phosphoglucose isomerase,* aldolase, glyceraldehyde-3-phosphate dehydrogenase,* phosphoglycerate kinase,* phosphoglycerate mutase, enolase, pyruvate kinase, lactate dehydrogenase, glucose-6-phosphate dehydrogenase, 6-phosphogluconic dehydrogenase, galactokinase, and galactose-1-phosphate uridyl-transferase
Decreased activity of phosphofructokinase*
Distribution of hexokinase isoenzymes differs from that of adults*

NONGLYCOLYTIC ENZYMES

Increased activity of glutamic oxaloacetic transaminase and glutathione reductase
Decreased activity of NADP-dependent methemoglobin reductase catalase,* glutathione peroxidase, carbonic anhydrase,* adenylate kinase,* and glutathione synthetase*
Presence of alpha-glycerol-3-phosphate dehydrogenase

ATP AND PHOSPHATE METABOLISM

Decreased phosphate uptake,* slower incorporation into ATP and 2,3-diphosphoglycerate*
Accelerated decline of 2,3-diphosphoglycerate during red blood cell incubation*
Increased ATP levels
Accelerated decline of ATP during storage or incubation

STORAGE CHARACTERISTICS

Increased potassium efflux and greater degrees of hemolysis during short periods of storage
More rapid assumption of altered morphologic forms during brief incubation*

MEMBRANE CHARACTERISTICS

Decreased ouabain-sensitive ATPase*
Decreased potassium influx*
Decreased permeability to glycerol and thiourea*
Decreased membrane filterability*
Increased sphingomyelin, decreased lecithin content of stromal phospholipids
Decreased content of linoleic acid*
Increase in lipid phosphorus and cholesterol per cell
Greater affinity for glucose*

OTHER CHARACTERISTICS

Increased methemoglobin content*
Increased affinity of hemoglobin for oxygen*
Glutathione instability*
Increased tendency for Heinz body formation in the presence of oxidant compounds*

*Appears to be a unique characteristic of the newborn's erythrocytes and not merely a function of the presence of young red blood cells.

Glucose and ATP production are increased, probably representing compensatory activity to maintain normal intracellular homeostasis by energy-dependent ion transport.[20] Several glycolytic enzymes demonstrate increased activity,[21] but this increase may reflect a larger percentage of younger RBCs in the neonatal circulation compared with the adult circulation rather than a characteristic specific to neonatal erythrocytes. Activities of other enzymes, including carbonic anhydrase and methemoglobin reductase, are reduced.

One important characteristic of the neonatal erythrocyte is increased susceptibility to oxidant-induced damage,[22-24] leading to glutathione instability, Heinz body formation, and methemoglobinemia. Alterations in the pentose phosphate pathway, decreased glutathione peroxidase,[25] diminished oxidant capacity of neonatal plasma, variations in superoxide dismutase levels, and decreased membrane sulfhydryl groups have all been implicated in the susceptibility of the neonatal erythrocyte to oxidative stress.[26] This increased susceptibility to oxidative injury may lead to hemolysis when severe hypoxia and acidosis is present in the fetus and newborn.[24]

Life Span

The life span of the erythrocyte in a term neonate is between 60 and 90 days, with preterm infants demonstrating even shorter life spans, from 35 to 50 days.[27] This shortened life span has been attributed to several properties specific to neonatal erythrocytes, including increased membrane deformability, more rapid loss of membrane surface area, increased susceptibility of membrane proteins and lipids to peroxidation, and a rapid decrease in intracellular enzyme activity and ATP content. When neonatal erythrocytes are transfused into adults, they exhibit a shortened life span that is attributed to the intrinsic differences between neonatal and adult erythrocytes. When adult erythrocytes are transfused into a neonate, they exhibit a normal life span.[28,29]

NORMAL HEMATOLOGIC VALUES

A number of factors influence hematologic values in the neonate, including many of the developmental changes previously listed. Interpretation of laboratory data in the neonate requires consideration of a number of factors, because a value that is normal for one infant may not be normal for another infant. The gestational and chronologic age of the infant, the infant's sex, timing of cord clamping, and the site of blood sampling are important factors to be considered.

Hemoglobin and Hematocrit

Hemoglobin concentration rises gradually throughout gestation and peaks shortly after birth.[30,31] The mean hemoglobin at 10 weeks' gestation is 9 g/dL, increasing to 11 to 12 g/dL by approximately 23 weeks and to 13 to 14 g/dL by 30 weeks' gestation (see Table 2-1).[2] Hemoglobin concentration is relatively stable the last 6 to 8 weeks of gestation, with a mean concentration 16 to 17 g/dL at term. Hemoglobin may increase by 1 to 2 g/dL at birth as a result of placental transfusion. Decreased plasma volume leads to a peak in hemoglobin between 2 to 6 hours of life, with levels stabilizing by 8 to 12 hours of age.

Erythropoiesis decreases at birth, leading to a gradual decrease in hemoglobin concentration during the next

TABLE 2-3 Normal Hematologic Values during the First 2 Weeks of Life in the Term Infant*

Value	Cord Blood	Day 1	Day 3	Day 7	Day 14
Hemoglobin (g/dL)	16.8	18.4	17.8	17.0	16.8
Hematocrit (%)	53.0	58.0	55.	54.0	52.0
Red cells (mm^3)	5.25	5.8	5.6	5.2	5.1

several weeks of life (Table 2-3). The nadir of hemoglobin concentration is reached at 8 weeks of life, with levels of approximately 11 g/dL in healthy term infants before erythropoiesis increases and the hemoglobin rises. This process is called *physiologic anemia* (discussed later).

Cord Clamping and Placental Transfusion

The timing of cord clamping significantly influences hemoglobin values in the newborn (discussed later).[30,32,33] Around the time of birth, placental blood is rapidly transferred to the infant. Approximately a quarter of this transfusion occurs within 15 seconds of birth and half occurs by the end of the first minute after birth. Delayed cord clamping (DCC) typically increases the infant's blood volume by 30%, because the placental vessels contain between 75 to 125 mL of blood at birth. Holding the infant above the level of the placenta prevents placental transfusion and may even lead to neonatal transfusion into the placenta, resulting in neonatal anemia.

Site of Blood Sampling

Significant variation in hemoglobin levels may exist, depending on the site of blood sampling.[30] Hemoglobin levels from capillary blood samples typically are higher than those obtained from indwelling venous or arterial catheters. Capillary samples may lead to overestimation of the hemoglobin, particularly when the samples are obtained from a poorly perfused extremity. The largest differences between capillary and venous hematocrits exist in very preterm infants,[34] particularly those with acidosis, hypotension, and anemia. In infants younger than 30 weeks' gestation, capillary hematocrit values are 20% higher than venous hematocrit values, compared with capillary values that are 12% higher than venous hematocrit levels at term. "Arterializing" a capillary sample by prewarming the extremity may improve the correlation between capillary and venous hematocrit levels. Finally, values of samples from similar sources, such as arterial, venous, and capillary samples, correlate independent of the site of sampling. For example, umbilical, radial, and femoral arterial hemoglobin levels show little variation from sample to sample.

Reticulocytes

Reticulocyte counts and the absolute reticulocyte count are elevated at birth, with values from 4% to 7% and 200,000 to 400,000/μL in term infants and 6% to 12% and 400,000 to 550,000/mL in preterm infants, respectively.[30] In healthy infants, the reticulocyte count falls over the first few days of life to levels of 0 to 1% by day 4 of life (see Table 2-3). A reticulocyte count of 0 on day 1 of life indicates that there is erythrocyte under production (discussed later).

Erythrocyte Indices

Mean Corpuscular Volume

The average volume of circulating erythrocytes is estimated by the MCV. During pregnancy an inverse relationship exists between gestational age and MCV, with MCV values decreasing throughout gestation to 108 to 118 fl at term (see Table 2-1).[2] When an MCV less than 95 fl is observed in a term neonate, α-thalassemia trait or iron deficiency should be considered.

Mean Corpuscular Hemoglobin

Similar to the MCV, the mean corpuscular hemoglobin is higher in preterm and term neonates, ranging from 33 to 41 pg/cell compared with 27 to 31 pg/cell in adults.

Mean Corpuscular Hemoglobin Concentration

The mean corpuscular hemoglobin concentration does not vary between neonates and adults. Although neonatal erythrocytes are larger and contain more hemoglobin, the hemoglobin in the erythrocyte is not more concentrated.

Erythrocyte Morphology

As previously noted, significant variations in neonatal erythrocyte morphology are commonly seen on peripheral blood smears, particularly in preterm infants, without intrinsic abnormalities of the erythrocyte. These variations include discocytes, bowls, echinocytes, and keratocytes (see Fig. 2-1).[3]

NEONATAL ANEMIA

Determining the cause of neonatal anemia can present a significant challenge. The differential diagnosis is extensive and includes not only many of the causes of anemia seen in older patients but also many causes unique to the fetus and newborn that are associated with pregnancy, labor, and delivery (Fig. 2-3). Knowledge of these disorders and an understanding of the associated

pathophysiology provide the appropriate context for the evaluation, diagnosis, and treatment of neonatal anemia. This chapter reviews anemia by etiology using the broad classifications of hemorrhage, hemolysis, and inadequate erythrocyte production.

HEMORRHAGE IN THE FETUS AND NEWBORN

Prenatal Hemorrhage

Fetal blood loss prior to birth is usually via the transplacental route, including fetomaternal hemorrhage (FMH), placental abruption, placenta previa, vasa previa, and twin-twin transfusion (Box 2-3).[35,36] Fetal blood loss, for instance due to intracranial hemorrhage in a thrombocytopenic infant with platelet isoimmunization or in a fetus after traumatic amniocentesis or cordocentesis, is less common.

Fetomaternal Hemorrhage (FMH)

FMH is the passage of fetal blood into the maternal circulation before or during delivery. Antenatal FMH is associated with variable effects on the fetus and neonate, ranging from none to neurologic injury, hydrops fetalis, and in utero demise of the fetus or, in the neonate, congestive heart failure (CHF), hypovolemic shock, persistent pulmonary hypertension, neurologic injury, and death.[36-38] The structure of the fetal-placental unit sets up a large pressure gradient from the umbilical artery to the intervillous space. The maternal intervillous space is separated from the pulsatile fetal circulation by a thin, two-cell membrane, with the constant possibility for rupture of the trophoblastic-endothelial juncture and contamination of the maternal intervillous space with fetal blood (Fig. 2-4, *A*). Given this very fragile mechanical relationship, it is surprising that significant FMH does not occur more frequently. Most spontaneous FMH occurs during the third trimester (Fig. 2-4, *B*), most commonly during labor and delivery,[39] although hemorrhage has been reported as early as 3 to 4 months' gestation (Fig. 2-4, C). Approximately 99% of deliveries are associated with FMH of less than 15 mL.[36] However, 3 in 1000 deliveries are associated with FMH greater than or equal to 30 mL, and 1 in 2000 pregnancies is associated with an FMH greater than or equal to 100 mL.[36,40]

Fetal RBCs can be detected in the maternal circulation in a number of ways. The most frequently used test is microscopic demonstration of fetal RBCs in the maternal circulation with use of the Kleihauer-Betke staining procedure.[17] With this method, HbA is denatured and eluted from smears of adult RBCs with an acid solution, leaving behind largely empty RBC membranes. Because HbF resists denaturation and elution, fetal cells stain darkly. Simple observation of the acid-treated maternal blood smear can provide a qualitative picture. The actual amount of fetal blood lost is estimated using the following formula: 2400 × the ratio of fetal to maternal cells = 1 mL of fetal blood.[41,42] Using this equation, it has been shown that most deliveries result in less than 3 mL of fetal blood in the maternal circulation, and only 0.3% have a fetomaternal transfusion of 10 mL or more. However, the volume of fetal blood in the maternal circulation does not reflect the timing or acuity of the hemorrhage.[36] Anti-HbF–based flow cytometry is an alternative method for detecting and quantifying cells that contain HbF in the maternal circulation.[36,43] Conditions that elevate maternal HbF production (e.g., thalassemia minor, sickle cell disease, hereditary persistence of HbF, and pregnancy-induced maternal HbF production) confound these analyses.[44] ABO blood group incompatibility can complicate interpretation of testing for FMH because removal of fetal cells from the maternal circulation by maternal anti-A or anti-B antibodies may lead to a false-negative result.

Abruptio Placentae

Placental abruption—that is, separation of the placenta from the uterine wall—occurs in approximately 1% of pregnancies. Abruption is more common in pregnancies

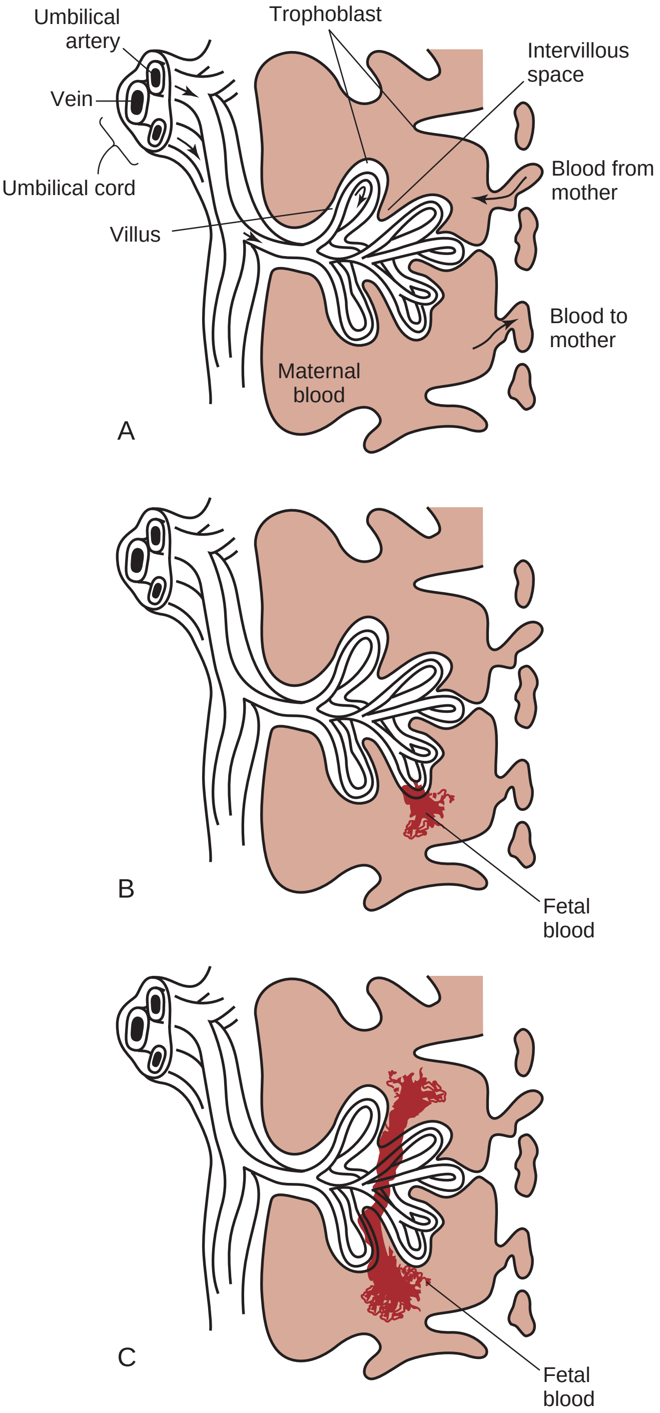

Figure 2-4 Anatomic issues in fetomaternal hemorrhage. **A,** Resting state: fragile capillary networks are present. **B,** A minor small bleed, known to occur in almost all pregnancies. **C,** A major possibility of significant exchange of fetal and maternal blood as a result of abruption (more severe) or normal childbirth.

complicated by chronic or pregnancy-induced hypertension.[31,45] The classic triad of placental abruption is vaginal bleeding, uterine contractions, and an irritable, tender uterus. If bleeding occurs in a retroplacental location, recognition and treatment may be delayed. Fetal hypoxemia may develop as a result of decreased placenta surface area and may be worsened by fetal hemorrhage accompanying the maternal bleeding. If fetal hemorrhage is significant, severe anemia, hypovolemia, and heart failure may rapidly develop, leading to in utero fetal demise.[46,47] Placental abruption is typically an acute event. However, fetal blood loss may occur gradually when the area of placental separation is small with a low-grade, chronic hemorrhage. At birth, these neonates exhibit anemia with compensation of varying degree, marked reticulocytosis, and prominent normoblastosis. In severe cases, iron deficiency may occur.

Placenta Previa

Placenta previa—that is, implantation of the placenta in a low-lying position in advance of the fetal presenting part, usually overlying part or all of the cervical os—occurs in approximately 1 in 250 births.[31,48] The classic presentation is acute onset of painless vaginal bleeding, with a peak incidence around 34 weeks' gestation. When placenta previa persists to the third trimester,[49,50] a cesarean section is indicated.[51] Fetal blood loss of varying amounts occurs in approximately 50% of cases. Signs of fetal anemia include intrauterine growth retardation, abnormal biophysical testing, and tachycardia. Vaginal bleeding may be intermittent and recurrent or massive and acute. In the former situation, the neonate presents with a partially or completely compensated anemia and marked reticulocytosis. In the latter situation, the neonate may present with acute hypovolemic shock with risk of death.[52] Up to 10% of neonates born after the occurrence of placenta previa exhibit significant anemia, making it the most common placental anomaly that causes neonatal anemia.[53]

Vasa Previa

Vasa previa occurs when fetal vessels exiting the placental end of the umbilical cord travel across the fetal membranes and then return to the fetal placental surface. If the fetal vessels are near the cervical os, they may tear when membranes rupture or during labor, when progressive cervical dilatation occurs. In both situations, laceration of the fetal vessels may lead to rapid exsanguination and death of the fetus.[54] Acute onset of vaginal bleeding (usually at the initiation of labor or during the progression of labor) with acute fetal tachycardia is a classic presentation of vasa previa. Prompt recognition of this condition, delivery, and resuscitation of the anemic infant are indicated to prevent peripartum death.[50]

Velamentous Insertion of the Cord

In cases of velamentous insertion of the cord, which occurs in approximately 1% of pregnancies, the umbilical vessels are unprotected and may tear spontaneously or during labor.[55] Rarely the unprotected umbilical vessel crosses the cervical os, combining a velamentous insertion with vasa previa, with a high potential for tearing when the membranes rupture.[56] Velamentous insertion is more common in twins and with low-lying placentas. The presentation of painless vaginal bleeding followed by signs of fetal distress is similar to vasa previa. The incidence of fetal loss is 1% to 2%.

Twin-Twin Transfusion and Related Disorders

Monochorionic twin pregnancies are at high risk for an adverse outcome because of vascular anastomoses that create shared fetal circulations. This situation may lead to complications, including twin-twin transfusion syndrome (TTTS), the twin anemia polycythemia sequence, the twin reversed arterial perfusion sequence, and monoamniotic twinning.[57-59] TTTS complicates 8% to 15% of twin gestations with monochorionic diamniotic placentation,[60,61] with the unbalanced transfer of blood from one fetus to the other via vascular anastomoses in the placenta.[62] Classically, the donor twin is small and anemic and the recipient is large and plethoric. Fetal demise may occur from exsanguination of the donor or circulatory overload in the recipient.[63] This condition may be dynamic with varying consequences to the twin fetuses, because the vascular anastomoses may vary in both size and number, as well as proceed in opposite directions.[64] Antenatal factors that may predict outcome include the presence of hydrops fetalis and gestational age.[65] Perinatal therapies have included serial amnioreduction, fetoscopic laser occlusion of communicating placental anastomoses,[66,67] maternal digoxin therapy, and selective feticide.[68,69]

At birth, both infants may be critically ill. The anemic donor twin may experience CHF and respiratory failure, whereas the plethoric recipient twin may require treatment for polycythemia hyperviscosity syndrome (PHS) and its complications, including thrombosis, hyperbilirubinemia, and, rarely, disseminated intravascular coagulation (DIC). In the classic presentation of TTTS in which the donor twin has been chronically hemorrhaging into the recipient, the donor anemic twin has marked reticulocytosis and normoblastosis, whereas the plethoric, polycythemic infant weighs greater than or equal to 20% more with a hemoglobin greater than or equal to 5 g/dL higher than its sibling. Acute transfusions, which typically occur closer to the time of delivery, do not lead to significant differences in neonatal weights, and there is an equal chance of either twin being the donor. Despite advances in pregnancy management, mortality in fetuses with TTTS remains high. The risk of long-term neurodevelopmental morbidity in survivors is significant.[70]

Traumatic Fetal Hemorrhage

Fetal bleeding has been described after multiple trauma and after blunt abdominal trauma to the pregnant mother.[71-73] It has also been described after traumatic amniocentesis or cordocentesis and after external cephalic version.[71-75]

Placental Lesions

The marked vascularity and unique double circulation of the placenta predisposes it to numerous vascular abnormalities, some of which may lead to fetoplacental hemorrhage and/or FMH.[76,77] Chorioangioma is the most common vascular anomaly of the placenta associated with neonatal anemia from fetoplacental hemorrhage and/or FMH. Chorioangiomas may number from one to many. In severe cases, they may lead to severe in utero hemorrhage and fetal demise.[78] Other placental lesions associated with neonatal anemia are hemangioma, hematoma, and intraplacental choriocarcinoma.[79-81]

Other Causes of Fetal Hemorrhage

In utero hemorrhage into fetal organs is uncommon,[82,83] with intracranial and intraabdominal hemorrhage predominating. Intracranial hemorrhage typically occurs when the pregnancy is complicated by thrombocytopenia (autoimmune or alloimmune), severe fetal hypoxemia, or maternal coumadin use.[84-87] Intraabdominal bleeding may occur after in utero volvulus, leading to ischemic bowel necrosis with venous hemorrhage.[88]

Intrapartum Hemorrhage

Hemorrhage due to events around the time of delivery is classified into cases involving the placenta and umbilical cord and cases related to neonatal trauma (see Box 2-3).

Placenta

Labor may exaggerate or worsen abnormalities of placentation (such as vasa previa, abruptio placentae, and velamentous insertion of the cord during labor) and lead to significant hemorrhage.

Laceration of the Placenta. An inadvertent placental incision during a cesarean section can lead to severe hemorrhage.[89,90] The risk of this complication is highest when the placenta is anteriorly placed and is lacerated during an emergency cesarean section or in cases in which placentation is unknown. Lower uterine incisions have also been associated with increased risk of placental injury.

Umbilical Vessels

One in 10,000 deliveries is associated with umbilical cord bleeding or rupture, which is associated with the risk of anemia, hypovolemic shock, and death. Cord rupture is most common in precipitous deliveries. Typically, traction on a shortened or abnormal umbilical cord leads to cord rupture, usually on the fetal side. Abnormalities such as cysts, vascular malformations (including aneurysms, hemangiomas, or varices), funisitis, or a velamentous insertion can weaken the cord and predispose it to rupture.[91] Entrapment of the cord accompanied by direct pressure, for example, by forceps, can also lead to traumatic cord laceration.

Neonates born with a tight nuchal cord can lose up to 20% of their blood volume into the placenta, leading to anemia and hypovolemic shock.[92] In cases of a tight nuchal cord, placental blood is blocked from flowing into the fetus by constriction of the thin-walled umbilical vein, while blood flow out of the fetus into the placenta via the muscular umbilical arteries continues.[93]

Intrapartum Trauma

Neonates may experience varying degrees of anemia as a result of internal bleeding associated with intrapartum trauma.[89] These internal hemorrhages may or may not be obvious at the time of delivery. In severe cases, signs of hypovolemic shock are seen shortly after birth. In other cases the infant may present with sudden pallor, tachycardia, and hypotension later on the first or second day of life. The site of internal bleeding may be discerned by the intrapartum history and other individual characteristics. Marked hyperbilirubinemia may occur.

Cranial Hemorrhage. Cranial hemorrhage is common in neonates because the head is typically the presenting part. Trauma to the scalp, the skull, or intracranial structures may result from traction applied manually—for example, by forceps or vacuum-assist devices. Cranial hemorrhage is associated with varying degrees of blood loss.

Subgaleal Hemorrhage. Bleeding into the subgaleal space usually occurs after a difficult, instrument-assisted delivery.[94,95] Trauma and/or traction tears of the emissary or "bridging" veins, which are connections between the dural sinuses and the scalp veins, leads to accumulation of blood in the potential space between the galea aponeurotica and the periosteum of the skull. The subgaleal space extends from the base of the skull forward to the orbital ridge and laterally to the temporal fascia and is thus able to accommodate significant amounts of blood.[96] Prompt recognition of subgaleal hemorrhage, with the finding of ballotable fluid in dependent regions of the head, is critical, and close monitoring should be provided. The degree of bleeding may lead to hypovolemic shock,[97] and exsanguination into a subgaleal hemorrhage with neonatal death has been reported. The occurrence of an extensive subgaleal hemorrhage should prompt evaluation for intracranial hemorrhage and neonatal coagulopathy.

Cephalohematoma. In cases of cephalohematoma, the hemorrhage is confined by the periosteum and limited to the area overlying a single bone of the skull. Giant cephalohematomas may result in neonatal anemia and hyperbilirubinemia.[98]

Intracranial Hemorrhage. Intracranial bleeding is most frequently found after a difficult delivery, in preterm infants, and in infants with disorders of coagulation, such as platelet isoimmunization or hemophilia.[99] Traumatic delivery leading to subdural, subarachnoid, and/or epidural hemorrhage may lead to anemia, even in term infants without coagulopathy. Preterm infants are at high risk for intraventricular hemorrhage,[100] which may approach 10% to 15% of the total blood volume. Although signs of acute blood loss may be present, anemia is rarely the only associated clinical finding.

Abdominal Hemorrhage. Traumatic intraabdominal hemorrhage is typically observed after a difficult delivery with prolonged traction and/or compression of the abdomen, particularly during breech extraction.[101] Patients may present with shock, abdominal distention, and discoloration of the abdominal wall or scrotum anytime from shortly after birth to up to 10 to 14 days of life. The diagnosis is suspected on the basis of the intrapartum history and clinical course, with confirmation by abdominal imaging—usually ultrasound. Some persons advocate repeat imaging of the abdomen after 12 to 24 hours to examine whether equilibration has occurred.

Adrenal Hemorrhage. Hemorrhage of the adrenal gland is uncommon in the neonatal period.[89,90] The adrenal gland is normally enlarged in the neonate, which, combined with its vascularity, predisposes it to birth trauma and hemorrhage. Adrenal hemorrhage may also occur in neonates with coagulopathy or infection or after acute hypoxia or asphyxia.[102] Adrenal hemorrhage has been associated with renal dysfunction, intestinal obstruction, and hyperbilirubinemia.[103] Bilateral adrenal hemorrhage, independent of the cause, can predispose the patient to adrenal collapse and an Addisonian crisis.

Hepatic Hemorrhage. Liver laceration, which occurs more frequently than recognized, is present in 1.2% to 5.6% of fetal and neonatal autopsies. Liver laceration may present immediately after birth or the infant may appear well for the first 12 to 24 hours of life because the hemorrhage is initially confined within the surrounding capsule.[104] When the hepatic capsule ruptures, hemoperitoneum, abdominal distention and discoloration, and hypovolemic shock rapidly ensue.[105] In some cases, a palpable mass in the right upper quadrant is present. Aggressive resuscitation and prompt surgical intervention have been lifesaving in affected neonates, but mortality is high.[106]

Splenic Hemorrhage. Splenic rupture may occur after traumatic delivery of a normal infant or after delivery of an infant with marked splenomegaly.[107] Splenic enlargement may be due to a congenital infection or extramedullary hematopoiesis—for example, as a result of erythroblastosis fetalis. Rupture may occur at delivery or later.[108] It has been reported to occur during exchange transfusion.[109] Symptoms of splenic rupture are similar to those of hepatic laceration.

Postpartum Hemorrhage

Neonatal Coagulopathy

Neonatal anemia may result from marked bleeding due to abnormalities in hemostasis, particularly at intracranial and gastrointestinal sites, or after trauma, such as circumcision. Disorders most commonly associated with significant hemorrhage in the neonate include congenital factor deficiencies, particularly hemophilia, and acquired and inherited platelet abnormalities.[110] Neonatal hemorrhage with secondary anemia has occurred in infants with vitamin K deficiency as a result of maternal anticonvulsant therapy or in exclusively breast-fed infants who were not treated with vitamin K at birth.[111] Neonatal anemia has also been reported in infants with Wiskott-Aldrich syndrome and thrombocytopenia–absent radius syndrome.

Iatrogenic Causes

Phlebotomy-associated blood loss leading to anemia may occur in hospitalized neonates, particularly premature infants. It is not surprising that these critically ill premature infants require the most phlebotomy procedures for diagnostic testing[112] or that they experience the most additional blood wastage (phlebotomy overdraw) during this testing.[113] Numerous noninvasive monitoring techniques and microscale laboratory analyses have been developed to avoid these phlebotomy-associated losses. Other iatrogenic causes of hemorrhage and anemia include vascular or tissue damage during diagnostic or therapeutic procedures, accidental disconnection of vascular catheters, and postoperatively associated with operative site or wound.

Other Causes of Hemorrhage

Gastric and intestinal ulceration with hematemesis or hematochezia may cause significant anemia in the neonate. The Apt test permits differentiation of neonatal blood from swallowed maternal blood. Hemorrhage into large tumors such as sacrococcygeal teratomas and bleeding from vascular malformations such as hemangiomas, hemangioendotheliomas, and arteriovenous malformations as causes of neonatal anemia have been described.[114-117]

Clinical Manifestations of Fetal and Neonatal Hemorrhage

Neonates are less tolerant of acute hypovolemia than are adults. Whereas an adult can tolerate a 10% loss of blood volume, a loss of this degree in the neonate results in significant peripheral and circulatory effects. Loss of greater than 20% of blood volume in the neonate leads to circulatory collapse, hypovolemic shock, and a high mortality rate. Symptomatology in neonatal hemorrhage is variable and is affected by the timing and amount of blood loss and the degree of resultant hypovolemia, if any (Table 2-4).

Hemorrhage prior to delivery may present as anemia without signs of hypovolemia. If adequate time has elapsed from the time of hemorrhage until delivery, reticulocytosis may be present, which may be confused with a hemolytic process. However, jaundice is not prominent, blood smear morphology is not suggestive of a hemolytic process, and the Coombs test is negative, all providing additional evidence for prenatal hemorrhage rather than hemolysis.

If the in utero blood loss is chronic, the neonate may be asymptomatic or present at birth with findings of CHF, including pulmonary edema, hepatomegaly, and peripheral edema, because over time, the fetus compensates for blood loss by increasing total blood volume. If the amount of in utero blood loss has been significant but has occurred over a protracted period, the neonate may be normovolemic but pale at birth, with hypochromic, microcytic erythrocytes on a blood smear indicating iron deficiency.

Neonates with significant acute blood loss at the time of delivery are pale, tachypneic, tachycardic, and have decreased pulses and hypotension. Pallor may be striking. Differentiation from other causes of pallor in the neonate is critical because immediate resuscitation with volume replacement is indicated to prevent circulatory collapse and death (Table 2-5).[90] When the neonate is in shock, a blood transfusion is indicated. In cases of acute hemorrhage, hemoglobin levels are a poor guide to

TABLE 2-4 Characteristics of Acute and Chronic Blood Loss in the Newborn

Findings	Acute Blood Loss	Chronic Blood Loss
Clinical	Acute distress; pallor; shallow, rapid, and often irregular respirations; weak or absent peripheral pulses; low or absent blood pressure; no hepatosplenomegaly	Marked pallor disproportionate to distress; occasionally signs of CHF are present; pulses are usually normal; blood pressure is usually normal; hepatomegaly
Venous pressure	Low	Normal or elevated
Hemoglobin	May be normal initially, then drops quickly in first 24 hours	Low at birth
RBC morphology	Normochromic and macrocytic	Hypochromic and microcytic, anisocytosis
Serum iron	Normal at birth	Low at birth
Course	Prompt treatment of anemia and shock required to prevent death	Generally uneventful
Treatment	IV fluids, blood, and iron therapy later	Iron therapy, occasionally pRBCs

CHF, Congestive heart failure; *IV,* intravenous; *pRBCs,* packed red blood cells; *RBC,* red blood cell.

diagnosis and therapy because hemodilution has not yet occurred and hemoglobin levels may not have fallen dramatically enough to immediately indicate that crystalloid volume replacement without transfusion is adequate.[89,90]

Supplemental iron should be provided to all infants with significant blood loss, acute or chronic, to replace lost stores.

HEMOLYSIS IN THE FETUS AND NEWBORN

Hemolytic processes are common causes of anemia in the neonate (Box 2-4). As with adults, it is useful to classify hemolytic disorders as extrinsic or intrinsic. Specific hemolytic disorders are discussed in detail in other chapters. Elements specific to the fetus and newborn are discussed in this section.

Extrinsic Hemolysis

Blood Group Incompatibility

Immune-mediated hemolytic anemia due to blood group incompatibility is the most common cause of hemolytic anemia in the newborn period. Details of fetal and neonatal immune hemolytic disease are provided in Chapter 3.

Other Causes of Extrinsic Hemolysis

Hemolytic anemia is present in some neonates born to mothers with autoimmune disease, particularly systemic lupus erythematosus and rheumatoid arthritis.[118] Neonatal lupus syndrome is associated with the transplacental passage of maternal autoantibodies, including Ro/SS-A, Ro/SS-B, and La, as well as other poorly characterized

TABLE 2-5 Differential Diagnosis of Pallor at Birth

Feature	Asphyxia	Acute Blood Loss	Chronic Blood Loss	Hemolytic Disease
Respirations	Retractions, cyanosis	Rapid without effort	Little distress unless congestive heart failure	Rapid if congestive heart failure
Arterial blood pressure	May be elevated or decreased	May be elevated or decreased	Usually normal	Usually normal
Central venous pressure	Normal or elevated	Low	Normal or elevated	Usually normal
Hepatosplenomegaly	Organs may be pushed down by lungs	None	Hepatomegaly if congestive heart failure	Hepatosplenomegaly
Jaundice	Perhaps	If loss of blood into tissues (e.g., scalp)	Usually not	Yes
Hemoglobin	Normal	Normal initially, drops after 24 h	Low at birth	Low at birth
Red blood cell morphology	Normal	Normal/macrocytic	May be hypochromic microcytic	May have hemolytic morphology
Other	Responds to O_2 intrauterine	Weak pulses	—	May have positive direct Coombs test or positive family history

Box 2-4 **Etiology of Hemolysis in the Neonate**

EXTRINSIC HEMOLYSIS

- Isoimmunization
  - Rh sensitization
  - ABO
  - Others, such as Duffy, Kell, and Lewis
  - Maternal autoimmune disorders
  - Maternal medication use
- Microangiopathic Anemias
  - DIC
    - Sepsis
    - Congenital infection—TORCH, malaria
- Vascular—Related Causes
  - Kasabach-Merritt syndrome
  - Renal artery
  - Large vessel thrombosis
  - Severe aortic coarctation
  - Arteriovenous malformation
- Oxidant Exposure
- Other
  - Galactosemia
  - Prolonged or recurrent acidosis

INTRINSIC HEMOLYSIS

- Enzymopathies
  - Hexose monophosphate shunt abnormality, such as G6PD
  - Embden-Meyerhof defect (glycolysis), such as pyruvate kinase
  - Other
- Red Blood Cell Membrane Defects
  - Hereditary spherocytosis
  - Hereditary elliptocytosis and related disorders
  - Hereditary stomatocytosis
- Hemoglobinopathies
  - α-Thalassemia syndromes
  - β-Globin cluster deletions
  - Unstable hemoglobins

DIC, Disseminated intravascular coagulation; *G6PD,* glucose-6-phosphate dehydrogenase; *TORCH,* toxoplasmosis, rubella, cytomegalovirus, and herpes virus infections.

contributing factors.[119] Clinical findings may include cutaneous lesions, congenital heart block, thrombocytopenia, anemia, neutropenia, hepatobiliary disease, and pericarditis.[120,121] With the exception of heart block, which is permanent, clinical manifestations, including anemia, are self-limited.[122]

Maternal autoimmune hemolytic anemia has led to neonatal anemia of varying degree with a positive direct antiglobulin test.[123-125]

Cases of maternal medication administration (including penicillin) reported to cause hemolytic anemia in the newborn have been described.

Angiopathic Anemias

Disseminated Intravascular Coagulation. Disseminated intravascular coagulation (DIC), which is commonly associated with anemia in neonates, occurs most frequently in association with systemic infection. DIC may complicate neonatal sepsis, particularly sepsis due to group B streptococcus, *Escherichia coli*, or *Pseudomonas aeruginosa*. Congenital infections due to cytomegalovirus, toxoplasmosis, syphilis, rubella, herpes simplex, and human immunodeficiency virus (HIV) have been associated with neonatal hemolytic anemia, with or without DIC.[31,121,126-128] Such cases may present a diagnostic dilemma when other causes of hemolysis are not found. Differentiating these common disorders clinically can be an aid to diagnosis (Table 2-6). Neonatal enteroviral infection has been complicated by DIC and anemia.[129] Although typically associated with hypoplastic anemia, parvovirus B19 infection may present with hemolysis as well (discussed later).

Neonates with necrotizing enterocolitis and infection with *Clostridium welchii* or *Clostridium perfringens* have experienced the acute development of severe, rapidly progressive intravascular hemolysis. This condition may lead to hemolysis of the entire RBC mass with acute renal failure, hypovolemic shock, and death.[130,131] These clostridial organisms produce several hemolytic toxins, one of which cleaves sialic acids from erythrocyte membrane glycoproteins, thus forming and exposing the Thomsen-Friedenreich cryptoantigen (or T antigen).[132] Anti-T antibodies are present in almost all adult plasma, and thus transfusion of adult blood to a neonate lacking T antibodies can lead to life-threatening hemolysis.

Vascular-Related Causes, Including Kasabach-Merritt Syndrome. Neonatal hemolytic anemia with microangiopathic changes has been associated with arteriovenous malformations, cavernous hemangiomas, renal artery stenosis, severe coarctation of the aorta, and large vessel thrombi. Kasabach-Merritt syndrome, a local consumptive coagulopathy with microangiopathic anemia, thrombocytopenia, and hypofibrinogenemia in association with significant vascular malformations, typically presents in the neonatal period.[133,134] The coagulopathy and anemia, which may be persistent and severe, improve with regression or removal of the malformation.

Oxidant Exposure

Oxidant hemolysis in the newborn is not rare, and it is not always associated with an inherited metabolic abnormality of the erythrocyte (see Chapters 17 and 18) or with congenital Heinz body anemia (see Chapter 19). An acute hemolytic event occurs, presumably related to the oxidant sensitivity of neonatal red cells. Infants present with acute onset anemia and hyperbilirubinemia with “bite” and “blister” cells, spherocytes, and irregularly shaped RBCs on a peripheral blood smear. Typically no obvious source for the presumed oxidant stress is identified and the episode resolves in a few days. Transfusion is rarely required. Infants with ongoing hemolysis warrant further diagnostic evaluation (see Chapters 18 and 19).

Other Causes of Hemolysis

Other causes of neonatal hemolysis include galactosemia, prolonged or recurrent metabolic acidosis, lysosomal storage disease, and some amino acidopathies. Although typically associated with a hypoplastic anemia and thrombocytopenia, hemolysis may be found in neonates with osteopetrosis. Maternal ingestion of valproic acid has caused hemolysis and thrombocytopenia in a breastfed infant.[111]

TABLE 2-6 Diagnostic Features of Some Transplacentally Acquired Infections Compared with Erythroblastosis Fetalis

Intrinsic Hemolysis

Disorders of Erythrocyte Metabolism

Congenital nonspherocytic hemolytic anemia includes disorders not attributed to immune-mediated disturbances, defects of hemoglobin or the erythrocyte membrane, or other disorders. The disorders in this heterogeneous group are caused by a variety of metabolic abnormalities of the erythrocyte, including enzymopathies of glucose, glutathione, and nucleotide metabolism (see Chapters 17 and 18). Significant clinical, laboratory, and genetic heterogeneity exists within individual disorders. Hemolysis develops as a result of enzyme or antioxidant deficiency or impaired enzyme function.

Disorders of the Hexose Monophosphate Shunt and Associated Pathways

Disorders of the hexose monophosphate shunt or the glutathione metabolic pathways impair the ability of the erythrocyte to adequately respond to oxidant stress. In the normal erythrocyte, reduced glutathione detoxifies intracellular oxidants. In glucose-6-phosphate dehydrogenase (G6PD) deficiency, the inability to generate reduced nicotinamide adenine dinucleotide phosphate leads to inadequate levels of reduced glutathione, leaving oxidants free to damage critical erythrocyte proteins. Oxidation of the sulfhydryl groups of hemoglobin produces functionless methemoglobin and intracellular precipitates of hemoglobin called Heinz bodies.[135]

Three clinical syndromes have been described in patients who are deficient in G6PD: neonatal jaundice (NNJ), congenital nonspherocytic hemolytic anemia, and acute hemolysis after an oxidative stress.[136] All three have been observed in the neonatal period.[136] NNJ, which is rarely present at birth, has a peak onset between the second and third day of life. The severity of hyperbilirubinemia is variable, but it may be severe, resulting in kernicterus or even death.[137] Hyperbilirubinemia is usually adequately treated with phototherapy,[138] but occasionally exchange transfusion is necessary. Anemia is rarely severe in neonates with NNJ, and when it is observed, it should prompt investigation for additional abnormalities.[139] The cause of NNJ in neonates with G6PD deficiency is unknown. Contributions from decreased hepatic excretion of bilirubin, low-grade hemolysis, or manifestation of an additional genetic disorder have been suggested.[140] The incidence of NNJ is increased in infants who are deficient in G6PD, with a polymorphism of the uridine diphosphoglucuronosyl transferase gene (*UGT1A*) associated with Gilbert syndrome (see Chapter 4).[141]

Hemolytic anemia, even with nonimmune hydrops fetalis, has occurred in the G6PD-deficient fetus or neonate after maternal ingestion of an oxidant agent such as a sulfa drug, ascorbic acid, or fava beans.[142-144] Hemolysis has occurred in breastfed, G6PD-deficient infants after maternal ingestion of fava beans.[145-147] These cases have led to the term *favism by proxy*.

Significant hemolysis after transfusion or exchange transfusion with G6PD-deficient erythrocytes in neonates has been described.[148,149] In areas endemic for G6PD deficiency, it has been recommended that blood donors be screened for G6PD deficiency prior to neonatal transfusion.

The diagnosis and treatment of G6PD deficiency is discussed in Chapter 18.

Disorders of the Embden-Meyerhof Pathway

Defects of the Embden-Meyerhof pathway are inherited in an autosomal-recessive fashion, and typically hemolysis is only seen in homozygotes or compound heterozygotes. An exception is phosphoglycerate kinase, an X-linked disorder in which hemolysis is only seen in affected males.

Pyruvate kinase deficiency, which is the most common abnormality of the Embden-Meyerhof pathway, usually presents in the neonatal period or early childhood with anemia and jaundice (see Chapter 17). Severe cases have presented with anemia in utero or in the first days of life.[150,151] Nonimmune hydrops fetalis has been described.[150] Neonatal hyperbilirubinemia is common in persons deficient in pyruvate kinase, and phototherapy or exchange transfusion may be required.[152] Kernicterus has been reported.

Other abnormalities of the Embden-Meyerhof pathway may present in the neonatal period.[19] Glucose phosphate isomerase deficiency is the third most common hemolytic enzymopathy and is frequently manifested in infancy. Marked fetal and neonatal anemia, nonimmune hydrops, hyperbilirubinemia, and perinatal death have been described.[153] Patients with hexokinase deficiency have experienced neonatal anemia and hyperbilirubinemia. Similarly, NNJ and anemia have been associated with 2,3-biphosphoglycerate mutase deficiency and phosphoglycerate kinase deficiency.

Disorders of Glutathione Metabolism

Deficiency of γ-glutamylcysteine synthetase and glutathione synthetase, enzymes involved in erythrocyte glutathione synthesis, has been associated with anemia in the neonatal period.[154,155]

Disorders of the Erythrocyte Membrane

Disorders of the erythrocyte membrane (see Chapter 16) make up an important group of hemolytic anemias that may present in the fetal or neonatal period. HS, hemolytic hereditary elliptocytosis (HE), and hereditary pyropoikilocytosis are the membrane disorders most likely to present in the fetus and newborn.

Hereditary Spherocytosis. HS frequently presents in the neonatal period with anemia and jaundice.[156,157] Other findings include pallor, jaundice, tachypnea, and poor feeding. Anemia is present in more than half of patients and may require transfusion. Neonates with HS typically experience more significant hemolysis than do adults. Alterations in the neonatal intraerythrocytic environment, microcirculatory effects, and decreased membrane stability due to destabilization of the membrane junctional complex by elevated levels of 2,3-DPG all may worsen hemolysis.[158] In addition, the shorter life span of the neonatal erythrocyte and the sluggish response of the marrow to erythropoietic stress in the first year of life contribute to the anemia. A longitudinal study of 23 infants with HS from birth to 1 year demonstrated an inadequate reticulocyte response and the need for transfusion in the first few months of life that gradually improved.[159] Severe HS cases with in utero anemia and nonimmune hydrops fetalis have been described.[160,161]

Hyperbilirubinemia, which is present in more than half of neonates with HS, occurs in the first few days of life. Levels of bilirubin may rise rapidly. Kernicterus has been described, and exchange transfusion may be required.[156] Similar to G6PD deficiency and other inherited anemias, co-inheritance of the Gilbert syndrome *UGT1A* gene polymorphism may accentuate hyperbilirubinemia in neonates with HS.[162]

Hereditary Elliptocytosis, Hereditary Pyropoikilocytosis, and Related Disorders. HE rarely presents in the neonatal period. The exceptions are hemolytic HE and hereditary pyropoikilocytosis[163] in which hemolysis, anemia, and jaundice may be severe, requiring treatment with phototherapy and blood transfusion.[164-166] Elliptocytosis, pyknocytosis, and fragmented cells may be prominent on a peripheral blood smear.[167,168] In most infants with hemolytic HE and hereditary pyropoikilocytosis, hemolysis wanes during the first year of life and typical HE proceeds to develop in the child with minimal to no anemia. Many of these patients have parents with typical HE and thus are homozygotes or compound heterozygotes for defects inherited from each of the parents. Southeast Asian ovalocytosis, a common HE syndrome in Southeast Asia and the South Pacific, usually presents with neonatal anemia and hyperbilirubinemia.[169]

Hereditary Stomatocytosis Syndromes

The hereditary stomatocytosis (HSt) syndromes are a heterogeneous group of disorders characterized by variable numbers of stomatocytes on a peripheral blood smear and abnormal permeability of erythrocytes to sodium and potassium, with resultant modification of intracellular water content.[170] HSt has presented in the neonatal period with severe hemolysis, anemia, hyperbilirubinemia, and hydrops fetalis. The dehydrated variant of HSt, hereditary xerocytosis, may present in utero with nonimmune hydrops fetalis unrelated to the degree of fetal anemia.[171,172] Hereditary xerocytosis has been linked to mutations in the mammalian mechanosensory transduction protein PIEZO1.[173,174]

Hemoglobin Disorders

Significant variation exists in the fetal and neonatal manifestations of α- and β-thalassemia because of developmental differences in globin chain synthesis. α-Globin synthesis is found in the yolk sac by 3 weeks' gestation. By 9 weeks' gestation, α-globin is the main α-like globin in the fetus, with only low levels of the major embryonic α-like embryonic hemoglobin, hemoglobin Portland ($\zeta_2\gamma_2$). In contrast, the switch from fetal to adult β-like globin chains, γ to β-globin, is not complete until 6 to 12 months of life. The primary hemoglobin in fetal and neonatal life is fetal hemoglobin, HbF ($\alpha_2\gamma_2$). Thus abnormalities of α-globin, such as homozygous α-thalassemia, lead to severe anemia in utero, whereas abnormalities of β-globin, such as homozygous β-thalassemia, are typically ameliorated in the first few months of life by sustained production of HbF. (See Chapter 21 for a detailed discussion of the thalassemias.)

α-Globin Defects

Clinical severity of the α-thalassemia syndromes is related to the numbers of functional α-globin genes present.[175,176] Deletion of a single α-globin gene results in a clinically silent asymptomatic carrier state. Deletion of two α-globin genes results in α-thalassemia trait with marked microcytosis, hypochromia, and mild anemia. Deletion of three α-globin genes results in hemoglobin H (Hb H) disease (see the section on Hb H disease in this chapter) with varying degrees of anemia, ranging from mild to severe.[177] Deletion of all four α-globin genes results in homozygous α-thalassemia, which usually leads to death of the affected fetus in utero from severe hemolytic anemia, CHF, and nonimmune hydrops fetalis.

Homozygous α-Thalassemia. In homozygous α-thalassemia, the major hemoglobin present is a tetramer of unpaired non-α chains, γ_4, or hemoglobin Bart's. Survival of the homozygous fetus to late gestation depends on the presence and amount of embryonic hemoglobin Portland. In the rare case where the child is born alive, death from cardiopulmonary collapse usually occurs shortly after birth. Advances in prenatal genetic diagnosis, interventional obstetric practice, and neonatal critical care have altered the clinical course of patients with homozygous α-thalassemia.[178,179] Genetic screening of at-risk populations, particularly Southeast Asians, has allowed identification of couples at risk for conceiving an affected fetus. In more than a dozen cases of homozygous α-thalassemia, careful pregnancy surveillance, in utero transfusion therapy, and postnatal transfusion therapy with iron chelation have led to prolonged survival.[179-181] Concerns about congenital malformations and potential long-term neurologic effects of prolonged intrauterine hypoxia exist.[178] Similar to some patients with β-thalassemia, bone marrow transplantation may provide a potential cure for these patients.

Hb H Disease. Infants with Hb H disease present with hypochromic, hemolytic anemia with microcytosis and RBC fragmentation.[175,178] Neonatal hyperbilirubinemia may be severe.[182] Hydrops fetalis has been described in cases of nondeletional Hb H disease.[183,184] Hemoglobin electrophoresis demonstrates hemoglobin H (β_4) and hemoglobin Bart's ($^{\gamma}4$). The differential diagnosis of neonatal microcytosis, with or without anemia, includes Hb H disease, acute-on-chronic fetomaternal hemorrhage with iron deficiency, or early presentation of α-thalassemia trait. Family history and ethnic origin (such as Southeast Asian), pregnancy history, maternal Kleihauer-Betke testing, and neonatal hemoglobin electrophoresis will clarify the diagnosis.

β-Globin Defects

As previously noted, structural variants of β-globin, including β-thalassemia and sickle cell disease, typically do not present with neonatal anemia. However, the incidence of neonatal hyperbilirubinemia in sickle cell disease is increased. In one rare case of sudden infant death in an infant with sickle cell disease, widespread neonatal vasoocclusion was observed.[185]

γδβ and εγδβ Thalassemia. Large deletions of the β-globin gene cluster may lead to the phenotype of γδβ and εγδβt halassemia.[186-188] These patients frequently present as neonates with a hypochromic hemolytic anemia with prominent normoblastosis. Over time, the anemia improves and the erythrocyte morphology evolves to that similar to β-thalassemia trait.

Unstable Hemoglobins

Unstable hemoglobins (see Chapter 19) due to abnormalities in the α-globin or the β-globin chain have been reported to cause NNJ and hemolytic anemia. Precipitated globin chain fragments form Heinz bodies, thus the name *congenital Heinz body hemolytic anemia*. Two interesting representative hemoglobin variants that present with hemolytic anemia in the neonate due to congenital Heinz body hemolytic anemia are hemoglobin Hasharon and hemoglobin F Poole. Hemoglobin Hasharon is due to a mutation in the α-globin chain such that, when mutant α-globin chains are paired with γ-globin, an unstable hemoglobin is produced.[189] When mutant α-globin chains are paired with β-globin, it is no longer unstable, presumably because of the tenfold higher affinity between α and β chains than between α and γ chains. Hemoglobin F Poole is an unstable hemoglobin due to mutation in the γ-globin chain.[190] As might be expected, Hemoglobin Hasharon, hemoglobin F Poole, and other hemoglobin variants influencing HbF structure and function produce hemolytic anemia in the neonatal period that resolves as the fetal-to-adult hemoglobin switch occurs.

DECREASED ERYTHROCYTE PRODUCTION

Decreased erythrocyte production is an uncommon cause of neonatal anemia. The etiologies of this state can be classified as genetic syndromes,[191] bone marrow replacement syndromes, or infectious suppression, or they may be due to other rare causes (see Chapters 6 and 7; Box 2-5).

Genetic Syndromes

Diamond-Blackfan Anemia

Diamond-Blackfan anemia (DBA) is a congenital, pure RBC aplasia often diagnosed before the age of 6 months (see Chapter 7).[191-193] Thirteen percent to 16% of children

Medications to mother or neonate
"Late" hyporegenerative anemia of Rh disease or other blood group antigens

affected with DBA are diagnosed at birth. Prenatal manifestations of severe anemia such as hydrops fetalis have been described, but they are rare in fetuses with DBA.[194-196,197,198] It has been suggested that fetal erythropoiesis is spared in utero or that the erythropoietic defect is rescued by a putative placental or maternal factor.[192] Growth retardation occurs in approximately one quarter of patients. A wide variety of nonhematologic abnormalities may be observed that bring the affected neonate to medical attention, including physical anomalies, particularly unusual thumb changes (bifid, triphalangeal, hypoplastic, or absent) or radial abnormalities (hypoplasia or absent pulse).[199,200] Less specific anomalies include microcephaly, a low hairline, hypertelorism, a flat nose, a cleft palate, a high-arched palate, retrognathia, low-set ears, and a webbed neck. Rarer abnormalities include genitourinary, cardiac (septal defects), and bony involvement.

Fanconi Anemia

Fanconi anemia,[201] an autosomal-recessive disorder involving a number of organ systems, is characterized by a steroid-responsive, hypoplastic macrocytic anemia with reticulocytopenia (see Chapter 7).[191,202,203] Diagnosis in the neonatal period rarely occurs as a result of anemia but instead is suggested by associated physical abnormalities,[204] including hypoplasia and/or aplasia of the thumbs and/or radii.[205] Other findings apparent in the neonatal period may include intrauterine growth retardation, genitourinary or cranial defects, and hyperpigmentation of the skin. It has been observed that patients with Fanconi anemia who are diagnosed in the neonatal period have a much higher incidence of multisystem involvement than do patients diagnosed later in life.[206]

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome is a rare autosomal-recessive disorder associated with exocrine pancreatic insufficiency, growth failure in the newborn period or early infancy, and bone marrow failure (see Chapter 7).[207,208] Affected patients have presented in the neonatal period with neutropenia, thrombocytopenia, and/or anemia,[209] as well as thoracic abnormalities.[210] Aplastic anemia may develop in up to 25% of patients.

Pearson Syndrome

Pearson syndrome, a rare mitochondrial deoxyribonucleic acid deletion disorder, is associated with anemia, metabolic acidosis, and exocrine pancreatic insufficiency as a result of the deficiency of several enzymes involved in oxidative phosphorylation (see Chapter 7).[211-214] Affected patients occasionally lack the metabolic derangements and present only with sideroblastic anemia. Macrocytic anemia is present in the neonatal period in a quarter of patients and by 6 months of age in about three quarters of patients.[215] Nonimmune hydrops fetalis has been described. Neutropenia and thrombocytopenia, usually in a mild form, may also be present.[216]

Aase Syndrome

Aase syndrome is a very rare congenital hypoplastic anemia with abnormally digitized thumbs that may present in the neonatal period.[217] Growth failure and other bony abnormalities may occur.[218]

Congenital Dyserythropoietic Anemia

Congenital dyserythropoietic anemia (CDA) is the name given to a group of rare disorders characterized by ineffective erythropoiesis and anemia with distinct abnormalities of cellular architecture as seen on electron microscopy (see Chapter 7). Although not technically a bone marrow failure syndrome, CDA results in anemia with ineffective reticulocytosis. Three primary subtypes and numerous variants of CDA have been described.[219]

Type I CDA (CDA-I), characterized by megaloblastoid erythroid hyperplasia and distinct chromatin bridges between cells, is due to mutations in codanin-1.[220] Approximately half of infants with CDA-I present in the neonatal period with anemia, and occasionally they present with nonimmune hydrops fetalis and hyperbilirubinemia.[219,221-223] Nonhematologic manifestations of CDA-I identified in the neonatal period include intrauterine growth retardation, syndactyly, and other bony abnormalities.

Type II CDA (CDA-II) is the most common variant of CDA. It is characterized by multinuclear late erythroblasts and one positive acidified serum test and is due to mutations in *SEC23B*.[221,224] One study of patients with CDA-II revealed that approximately one quarter of patients had severe anemia in the neonatal period.[225] Hyperbilirubinemia was common, and exchange transfusions were required in a few cases. Nonimmune hydrops fetalis has been observed in patients with CDA-II.[226]

Type III CDA, which is characterized by multinuclear erythroblasts and macrocytosis and associated with mutations in *KIF23*, has presented in the neonatal period with anemia and hyperbilirubinemia.[227]

Patients with variant CDA due to mutations in erythroid transcription factors have presented in the perinatal period. Infants with X-linked anemia and thrombocytopenia due to a mutation in the erythroid and megakaryocyte transcription factor GATA1 have been described.[228-230] Affected male fetuses experience severe fetal anemia with nonimmune hydrops fetalis and require in utero transfusion. Neonatal thrombocytopenia and anemia are present, and marrow examination shows dyserythropoiesis. Infants who have severe fetal anemia with nonimmune hydrops fetalis and neonatal anemia associated with a mutation in the second zinc finger of the erythroid transcription factor KLF1 have been described. Affected patients experience hemolysis and ineffective erythropoiesis with elevated HbF and changes in numerous membrane proteins, including several blood group antigens.[231-233]

Variant CDA with extramedullary erythropoiesis presenting in the neonatal period has been described in patients with mevalonate kinase deficiency.[234,235] Other symptoms include intrauterine growth retardation, dysmorphic features, skeletal anomalies, cholestatic liver disease, diarrhea, and failure to thrive.[236]

Dyserythropoietic anemia presenting in infancy, along with exocrine pancreatic insufficiency and calvarial hyperostosis, has been reported due to mutations in COX412, a structural component of the cytochrome c oxidase complex.[237]

Bone Marrow Replacement Syndromes

Anemia can develop as a secondary effect of bone marrow replacement. This symptom has been observed in cases of transient myeloproliferative disorder (TMD) and is frequently associated with trisomy 21 (see Chapter 50), congenital leukemia (see Chapter 51), and osteopetrosis.

Transient Myeloproliferative Disorder

TMD is characterized by the proliferation of myeloblasts in the marrow and blood of affected newborns, mimicking congenital leukemia and leukemoid reaction.[238] It is typically observed in patients with trisomy 21. In contrast to congenital leukemia, spontaneous remission occurs early in infancy. Anemia and thrombocytopenia are commonly observed. Cases of TMD with nonimmune hydrops fetalis have been described.

Congenital Leukemia

True malignant congenital leukemias have been associated with in utero fetal demise, nonimmune hydrops fetalis, fetal or neonatal anemia, and thrombocytopenia.[239-242] Widespread infiltration of leukemic cells with visceral fibrosis due to megaloblastic proliferation in the liver has been described in cases of both TMD and congenital leukemia.[239,240,243]

Osteopetrosis

Osteopetrosis is a heterogeneous group of disorders.[244] Recessive malignant forms of osteopetrosis may present in the neonatal period with hepatosplenomegaly, craniomegaly, bony sclerosis, and disordered hematopoiesis, including progressive anemia.[244,245,246,247] The failure of osteoclasts to resorb and remodel bone leads to progressive ablation of the bone marrow cavity and extramedullary hematopoiesis in the spleen and liver and a progressive macrocytic anemia with reticulocytosis. Early bone marrow transplantation has been successfully used to treat these patients.[246,248]

Other Replacement Syndromes

Fetal and neonatal anemia has been described in cases of mucopolysaccharidosis type VII and neonatal hemochromatosis.[194]

Infectious Suppression

Congenital infection, in addition to hemolysis, may also lead to bone marrow failure in the neonatal period (see Box 2-5). A detailed discussion of associated infectious agents is beyond the scope of this chapter; however, infection with parvovirus B_{19} warrants discussion.

Parvovirus B_{19} Infection

Parvovirus B_{19} is the etiologic agent of erythema infectiosum (fifth disease),[249] a benign illness of children and adults that presents with fever, chills, vomiting, and diarrhea,[250] with the appearance of a maculopapular exanthem on the face (slapped-cheek syndrome) temporally associated with the abatement of the fever. Parvovirus B_{19} selectively infects erythroid precursors and inhibits their growth. Erythropoietic arrest leads to an acute decrease in hemoglobin with reticulocytopenia. Although this drop is tolerated by healthy children and adults, infection in susceptible pregnant women may bring about fetal infection,[251] leading to profound fetal anemia, nonimmune hydrops fetalis, and fetal demise.[252,253] Hydrops fetalis will develop in approximately 10% of fetuses whose mothers acquire a primary parvovirus B_{19} infection. If fetal demise does not occur, fetal anemia and the hydrops fetalis may gradually resolve. In utero transfusion has been successfully used to treat anemic, infected fetuses.[254,255]

When parvovirus B_{19} infection is suspected in an anemic, hydropic newborn, detection of parvovirus immunoglobulin M antibody in the infant, analysis of serial, paired fetal/maternal immunoglobulin G antibody, or detection of parvovirus protein or deoxyribonucleic acid in the neonate or placenta can confirm the diagnosis.[256] Typically the anemia associated with parvoviral infection resolves in 10 to 14 days, during which time supportive care is required. The long-term outcome of infants receiving in utero transfusion to treat parvoviral-induced anemia has been good.[257-259]

Other Causes of Erythrocyte Underproduction

Nutritional Anemia

Nutritional deficiencies are the most common cause of anemia in the first year of life, but they are an infrequent cause of anemia in the neonatal period.

Iron deficiency anemia is uncommon at birth. When present, it is most common in infants who have sustained significant chronic or acute prenatal blood loss, because approximately three quarters of the neonate's total body iron is stored as hemoglobin. Several factors contribute to the increased risk of preterm infants for iron deficiency, including rapid growth without adequate supplemental iron, iron losses due to phlebotomy, and their inability to regulate their iron status on the basis of physiologic needs with poor regulation of iron absorption and failure to increase gastrointestinal iron absorption despite decreased serum ferritin levels.[260]

Vitamin B_{12} deficiency has occurred in the breastfed infants of strict vegetarian mothers, in the infants of mothers with pernicious anemia, and in breastfed infants of mothers with chronic tropical sprue.[261,262] Vitamin B_{12} deficiency can also occur in infants with malabsorptive abnormalities or with inborn errors of vitamin B_{12} or related proteins, including deficiency of intrinsic factor, haptocorrin, or transcobalamin II.[263] Other related disorders that may be associated with vitamin B_{12} deficiency include the methylmalonic acidurias and deficiency of adenosylcobalamin or methylcobalamin (or both).

Folate deficiency is more likely to develop in preterm infants, in infants who are fed a folate-poor diet (including goat's milk or milk that has been boiled), and in infants with malabsorption. Other disorders associated with folate deficiency in infancy include congenital folate malabsorption, defective cellular folate uptake, and inborn errors of folate metabolism. Folate deficiency has also been reported in infants after exchange transfusion because the high levels of folate in the infant's blood have been replaced by normal adult values, which are relatively lower. The megaloblastic anemia of vitamin B_{12} or folate deficiency in infancy is similar to that observed in adults.

The sideroblastic, hypochromic anemia of copper deficiency, which is often associated with neutropenia, is rare in the neonatal period. Infants at risk for copper deficiency include preterm infants fed only milk, infants receiving prolonged parenteral nutrition without trace elements, and infants with chronic diarrhea and malnutrition.

Medications

Hypoplastic anemia has been observed in neonates born to mothers taking various medications. Administration of zidovudine (AZT) alone[264,265] and in combination with other antiretroviral agents[266-268] for the treatment of maternal HIV infection may result in a hyporegenerative neonatal anemia.

The Late Anemia of Rh Disease

In infants with Rh or Kell alloimmunization, a "late" anemia characterized by significant anemia with reticulocytopenia may develop at 1 to 3 months of age as a result of decreased erythrocyte production and/or continued destruction of reticulocytes from the persistence of maternal antibody.[269-271] This late anemia is found in infants who have received a transfusion and in infants who have not received a transfusion. Similar to anemia of prematurity (see related section in this chapter), relative reticulocytopenia is present despite elevated erythropoietin levels.[272] Transfusion may be required, particularly if the infant feeds poorly, has inadequate weight gain, and has persistent tachypnea or tachycardia. Although erythroid progenitors from these patients are responsive to erythropoietin in vitro, response to treatment with erythropoietin has been disappointing because its administration has failed to have an impact on the need for transfusion.

PHYSIOLOGIC ANEMIA AND ANEMIA OF PREMATURITY

Physiologic Anemia

Immediately after birth, a sudden increase in hemoglobin saturation occurs as the infant moves from maternal oxygenation to extrauterine circulation and pulmonary respiration. The degree of relative tissue hypoxia is dramatically altered, erythropoietin levels fall, and RBC production begins to decrease. Eventually, decreased oxygen-carrying capacity caused by decreasing hemoglobin concentration stimulates erythropoietin production, leading to increased RBC production and a higher hemoglobin concentration. Term infants experience this gradual decrease in hemoglobin concentration during the first 8 to 12 weeks of life (Table 2-7). The hemoglobin concentration then remains stable for several weeks before gradually increasing. In term infants, this decline and rise in hemoglobin concentration has been termed *physiologic anemia*. These infants are asymptomatic, and this process appears to be a normal adaptation of the switch from intrauterine to extrauterine life.

Anemia of Prematurity

Preterm infants also experience this decline and rise in hemoglobin concentration. Although mean cord hemoglobin levels do not vary significantly between preterm and term infants, the decline in hemoglobin concentration occurs earlier in preterm infants, around 4 to 8 weeks of age, and to values significantly lower than those of term infants, with the nadir varying inversely with gestational age (Fig. 2-5; Table 2-8).[273] This dramatic decrease in hemoglobin may lead to symptomatic anemia requiring transfusion. This condition, characterized by normocytic, normochromic anemia; reticulocytopenia; bone marrow hypoplasia; and erythropoietin levels inappropriately low for the level of anemia, is nonphysiologic[274-276] and is termed the *anemia of prematurity*. The degree of anemia varies with the degree of prematurity, nutritional status and intake, chronologic age, and the type and severity of the underlying illness.

Pathogenesis

The pathogenesis of anemia of prematurity is multifactorial.[277,278] Preterm infants have a blunted response to erythropoietin, the primary growth factor for erythropoiesis. Hypoxia is the stimulus for erythropoietin production and secretion. After secretion erythropoietin travels via the blood to hematopoietic tissues where it stimulates

the proliferation and differentiation of erythroid cells. In the fetus, erythropoietin is produced primarily in the liver, with production switching to the kidney near term. The sensitivity of the mechanisms that sense hypoxia in the adult kidney are decreased tenfold in the fetal liver, and thus preterm infants have a decreased response to comparable levels of hypoxia and anemia compared with adults. Erythropoietin has greater clearance and a shorter half-life in preterm infants.[279,280] Other factors influencing hemoglobin concentration in the preterm infant include a shorter erythrocyte life span and dilution of hemoglobin by rapid growth. Continued phlebotomy and transfusion of adult blood with hemoglobin A further blunts the hypoxic stimulus for erythropoietin production and worsens anemia.

Diagnosis, Treatment, and Prevention

Infants thought to be symptomatic as a result of anemia of prematurity are reported to exhibit apnea, bradycardia, tachycardia, tachypnea, lethargy, poor feeding, increased oxygen requirement, and inadequate weight gain despite adequate caloric intake.[281,282] It has never been convincingly shown that symptoms of anemia are reduced after transfusion in a randomized, controlled prospective trial.[283-285] In fact, several studies have documented a lack of improvement in clinical status in transfused versus untransfused infants with anemia of prematurity,[286-289] leading to controversy regarding when—and at what levels—hemoglobin transfusion is indicated in preterm infants. Concerns about potential adverse effects of transfusion in preterm neonates, including transfusion-associated gut injury,[290-293] have led to further reexamination of the risks and benefits of transfusion therapy in this population.[294,295]

The success of erythropoietin therapy in decreasing transfusion in adult patients with end-stage renal disease offered a potentially novel treatment modality for anemia of prematurity. Pilot studies were encouraging, with erythropoietin enhancing erythropoiesis in anemic, preterm infants. At present, with more than 20 studies reported,[296] a consistent increase in erythropoiesis has been observed in erythropoietin-treated preterm neonates but without a consistent reduction in transfusions. Reviews of controlled clinical trials analyzing the efficacy of erythropoietin in reducing blood transfusions in infants with anemia of prematurity detected benefit across high-quality studies using conservative transfusion criteria, but the authors concluded that insufficient data were available to recommend erythropoietin therapy as standard treatment for anemia of prematurity.[297,298,299,300]

Retrospective analyses have raised concerns about the use of erythropoietin and the occurrence of severe retinopathy of prematurity in preterm infants.[301-303] Because previous studies were not designed to characterize the relationship between erythropoietin administration and retinopathy of prematurity, further studies have been proposed to address this issue.[304]

A more important goal than decreasing the number of blood transfusions in the treatment of infants with anemia of prematurity has been reducing the number of blood donors to which an infant is exposed.[305] This goal has led to the development of conservative transfusion criteria, decreases in phlebotomy-related losses, adoption of noninvasive monitoring technology, changes in

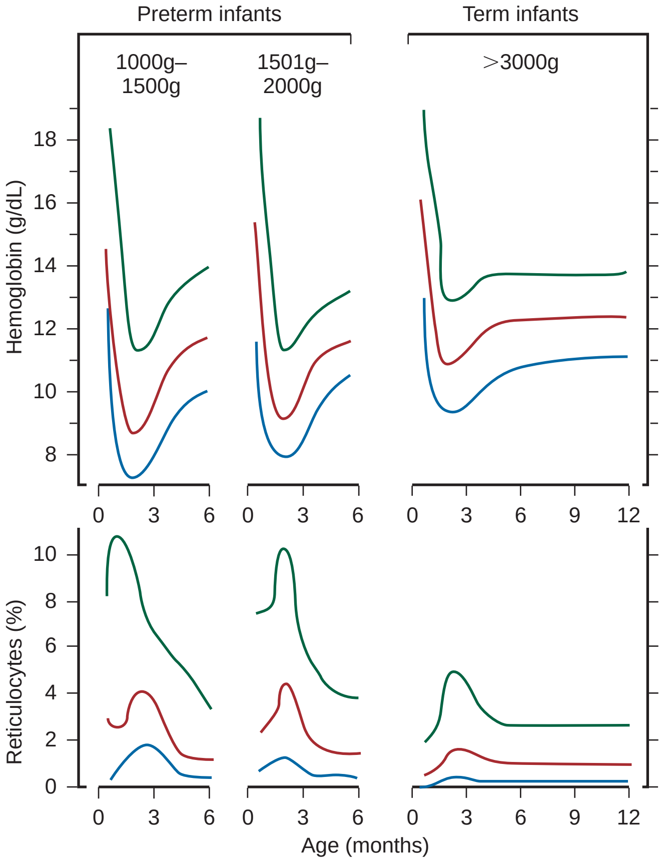

Figure 2-5 The mean upper *(green)* and lower *(blue)* ranges of normal hemoglobin and reticulocyte values for healthy and preterm infants. clinical practice, provision of adequate supplemental iron and early protein supplementation, and the use of dedicated units of erythrocytes in neonatal transfusion therapy.[278,306,307,308-310] A single-donor unit that can be used multiple times over a period of 42 days is dedicated to an individual infant to avoid multiple donor exposure.[311]

Resurging interest has recently been expressed in delayed umbilical cord clamping at the time of birth.[312] Delayed cord clamping (DCC) leads to an increase in neonatal blood volume of up to 30%.[313] In the term infant, DCC increases iron stores, thereby decreasing the risk of anemia.[314] In the preterm infant, DCC improves transitional circulation, decreases the need for and the number of blood transfusions to treat anemia, decreases the risk of intraventricular hemorrhage, and may decrease the risk of late onset sepsis and necrotizing enterocolitis.[315-317] The American College of Obstetricians and Gynecologists supports DCC in preterm but not term infants.[318]

APPROACH TO THE ANEMIC INFANT

Detailed evaluation of the anemic neonate combines history, physical examination, and laboratory investigation. Use of a diagnostic algorithm may facilitate evaluation (Fig. 2-6).

A detailed maternal history should be obtained that includes medical history with particular attention to anemia, jaundice, transfusions, gallstones, or splenectomy, as well as ethnicity. The obstetric history also should be obtained, including complications of labor and delivery and a history of anemia or jaundice in previously delivered infants. Details of the pregnancy should be

Figure 2-6 An approach to neonatal anemia. The asterisk indicates a smear with no predominant morphology. *CMV,* Cytomegalovirus; *DIC,* disseminated intravascular coagulation; *MCV,* mean corpuscular volume; *RBC,* red blood cell; *Retics,* reticulocyte count. *(From Oski F: Hematology: the erythrocyte and its disorders. In Nathan DA, Oski FA, editors:* Hematology of infancy and childhood, *ed 4, Philadelphia, 1993, WB Saunders, p. 38.)*

reviewed, including zygosity, medication use, history of vaginal bleeding, infections and exposure to infectious persons, exposure to oxidant compounds such as fava bean ingestion, and history of amniocentesis or trauma. Maternal blood type, antibody testing, and available hematologic data should be collected. Documentation of fetal status throughout the pregnancy should be obtained. The presence of congenital malformations, abnormal ultrasound findings, and amniocentesis and cordocentesis results, if performed, should be obtained.

Details of the labor and delivery including placentation, fetal distress, and history of external cephalic version should be sought. The route of delivery, use of instrumentation to assist extraction (such as forceps or vacuum-assist devices), breech delivery or difficult extraction, and the presence of a tight nuchal cord should all be noted. Placental or vaginal bleeding should be recorded. Placental findings should be collected.

A family history of anemia, jaundice, transfusions, gallstones, or splenectomy and paternal ethnicity should be sought.

The neonate's hospital course and available laboratory data should be reviewed. Particular attention should be directed to amounts obtained at phlebotomy, performance of invasive procedures, surgery, and the need for transfusion or phototherapy.

Physical examination begins with inspection of the placenta, umbilical cord, and vessels, with special attention to the integrity and insertion of the umbilical vessels, the presence of lesions of the cord or placenta, and the presence of placental abruption. Careful physical examination of the neonate should be undertaken with evaluation for pallor, jaundice, hepatosplenomegaly, and congenital anomalies.

The initial basic laboratory evaluation includes a blood cell count with erythrocyte indices, examination of a peripheral blood smear, a reticulocyte count, blood type, a direct antiglobulin test, and serum bilirubin determination.

A positive direct antiglobulin test indicates immune hemolysis. Neonatal and maternal blood types should be compared, and maternal serum should be evaluated for the presence of antibodies. A low reticulocyte count indicates inadequate RBC production. A maternal history of possible parvoviral infection should be sought and additional diagnostic testing should be pursued, if indicated. Microcytosis in an anemic infant suggests the presence of a hemoglobinopathy, Hb H disease or γδβ thalassemia, or recovery from chronic in utero hemorrhage. Hypochromia due to iron deficiency is common with chronic hemorrhage. Neonatal normoblastosis is prominent in infants who have experienced chronic hemorrhage and γδβ thalassemia. Hemoglobin electrophoresis and maternal Kleihauer-Betke testing can help differentiate these disorders.

The presence of hyperbilirubinemia and hemolysis on a peripheral blood smear in an infant with a negative antiglobulin test suggests an intrinsic erythrocyte defect. In some cases, such as HS, erythrocyte morphology on a blood smear may be suggestive of the diagnosis. Additional diagnostic evaluation is indicated. Serum haptoglobin is frequently low or undetectable in healthy infants without hemolysis and is not a useful adjunct in the investigation of neonatal hemolytic anemia.[319]

The infant with a normocytic, normochromic nonhemolytic anemia and a negative direct antiglobulin test should be suspected of having had acute blood loss. Maternal Kleihauer-Betke testing and placental examination should be performed. If the cause remains cryptic, ultrasonography of the head and abdomen to detect occult hemorrhage should be considered.

POLYCYTHEMIA HYPERVISCOSITY SYNDROME

Neonatal polycythemia is common; it occurs in 1% to 2% of live births at sea level and up to 5% of births at high altitude.[320-325] Numerous risk factors have been associated with the development of polycythemia, primarily associated with increased erythropoiesis due to fetal hypoxia or fetal erythrocyte transfusion. Reported risk factors include maternal diabetes, smoking, alcohol or substance use, hyperthyroidism, hypertension, or preeclampsia, intrauterine growth restriction, fetal trisomy or other genetic syndromes including Beckwith-Wiedemann syndrome, congenital adrenal hyperplasia and hypothyroidism,[326-337] maternal-fetal transfusion, twin-twin transfusion, delivery outside of labor and delivery, perinatal asphyxia, nuchal cord, cord stripping, and DCC.[338,339] Increased erythrocyte mass may lead to increased blood viscosity (Fig. 2-7), alterations in blood flow, and end organ damage, which results in a constellation of clinical and laboratory findings called PHS (Box 2-6).[326,340] In some (but not all) reports, infants with PHS have been reported to have worse developmental and neurologic outcomes than their nonpolycythemic counterparts.

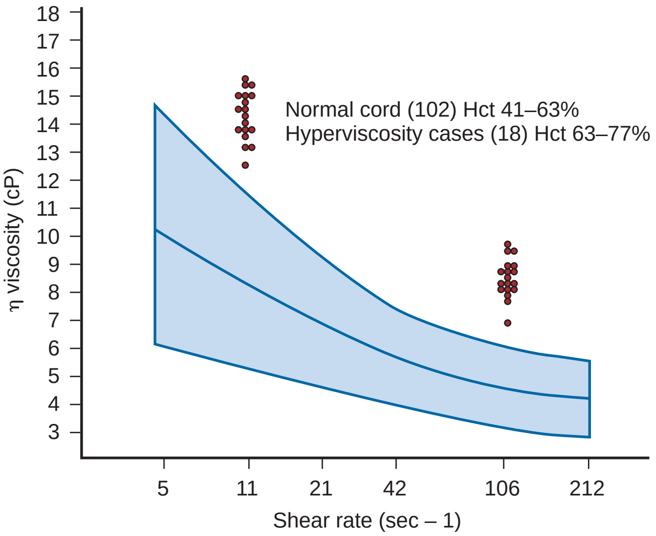

Figure 2-7 Blood viscosity versus hematocrit (Hct) in normal and polycythemic infants. The shaded area represents the viscosity of cord blood at shear rates from 2 to 212/s for 102 healthy term appropriate-for-gestational-age infants (mean ± 2 standard deviation). Viscosity for 18 "symptomatic" infants is plotted at shear rates of 11/s and 106/s. Hct values for each group are indicated. *(From Gross GP, Hathaway WE, McGaughey HR: Hyperviscosity in the neonate.* J Pediatr *83:1004–1012, 1973.)*

Partial exchange transfusion (PET) has been used in infants with PHS to relieve clinical symptomatology and potentially improve neurologic outcome by reducing the hematocrit. The rationale for PET is that decreasing presumed hyperviscosity decreases vascular resistance, improves tissue perfusion, limits end organ damage, and thereby prevents or ameliorates complications of PHS.[341-344] PET improves symptomatology, such as hypoglycemia, poor perfusion, cyanosis, and cardiac function.[345-348] However, it has not been convincingly shown to improve long-term developmental outcomes,[345,346,349] and it may be associated with complications of its own,[350] leading many persons to question the utility of PET.[351] The American Academy of Pediatrics

Box 2-6 **Findings Attributed to Neonatal Polycythemia Hyperviscosity Syndrome**

- Pulmonary hypertension
- Necrotizing enterocolitis
- Thrombotic/ischemic event

guidelines for PET in the treatment of PHS are: “The accepted treatment of polycythemia is PET. However, there is no evidence that exchange transfusion affects long-term outcome.”[352]

Studies providing guidance about when to perform PET for PHS are lacking, making it difficult to determine when and at what threshold of hematocrit a PET for PHS should be performed.[353] The standard in many hospital nurseries is to perform PET when the venous hematocrit is greater than or equal to 65% in an infant with symptoms of PHS or when the venous hematocrit is greater than or equal to 70% in an asymptomatic infant, although few data support this approach.[354] In some hospitals, PET is not performed in asymptomatic neonates until the venous hematocrit is greater than or equal to 75%. Adding to the controversy regarding the appropriate threshold of hematocrit is the observation that hematocrit is an imprecise surrogate of blood viscosity, making it a poor indicator of who needs PET. Polycythemia and hyperviscosity are not synonymous. In addition to hematocrit, many other factors such as plasma proteins, leukocytes, fibrinogen, platelets, blood pH, and erythrocyte deformability may influence blood viscosity.[326,328,355-358] The inability to directly measure blood viscosity in most hospitals has led to the adoption of hematocrit as a surrogate marker of blood viscosity. However, hematocrit is an imperfect measure of viscosity, because not all infants with an elevated hematocrit level have increased blood viscosity.[359] Given the risk of complications from both PHS and PET, a more precise test of blood viscosity is needed to better determine which patients might benefit from PET.

Several studies have demonstrated that symptomatic patients with PHS are at risk of adverse neurologic outcomes,[349,360,361] highlighting the need for careful developmental follow-up of these infants, even if they do not undergo PET. These data are consistent with the suggestion that in some patients, an adverse intrauterine environment or a significant perinatal event leads to tissue hypoxia, polycythemia, hyperviscosity, with irreversible tissue damage that would not be ameliorated by PET.[340,345,349] Given the potential risk of complications from both PHS and PET, a more precise test of blood viscosity is needed to better determine which patients might benefit from PET.

The clinical, laboratory, and genetic manifestations of disorders of cobalamin metabolism, also known as vitamin B12, are reviewed. Associated hematologic findings are also discussed.

268. Ziske J, Kunz A, Sewangi J, et al: Hematological changes in women and infants exposed to an AZT-containing regimen for prevention of mother-to-child-transmission of HIV in Tanzania. *PLoS ONE* 8(2):e55633, 2013.

Assessment of hematologic alterations in a cohort of HIV-positive, zidovudine-exposed women and their infants revealed transient anemia and granulocytopenia compared to nonzidovudine-exposed controls.

269. Thorp JA, O'Connor T, Callenbach J, et al: Hyporegenerative anemia associated with intrauterine transfusion in rhesus hemolytic disease. *Am J Obstet Gynecol* 165(1):79–81, 1991.

An infant who required in utero transfusions for severe Rh disease developed a hyporegenerative transfusion-dependent anemia that lasted 3 months. Anemia was attributed to erythropoietin suppression after fetal transfusions, toxic effect of anti-D antibody on erythroid precursors, and peripheral hemolysis of reticulocytes.

278. Strauss RG: Anaemia of prematurity: pathophysiology and treatment. *Blood Rev* 24(6):221–225, 2010.

The multifactorial nature of the anemia of prematurity is reviewed. Treatment, with RBC transfusion being the primary modality, is also discussed.

299. Aher SM, Ohlsson A: Early versus late erythropoietin for preventing red blood cell transfusion in preterm and/or low birth weight infants. *Cochrane Database Syst Rev* (10):CD004865, 2012.

Cochrane review of the early use of erythropoietin for anemia of prematurity did not significantly reduce the use of one or more RBC transfusions or the number of transfusions per infant compared with late erythropoietin administration. An increased risk of retinopathy of prematurity with early erythropoietin treatment was detected.

307. Carroll PD, Widness JA: Nonpharmacological, blood conservation techniques for preventing neonatal anemia—effective and promising strategies for reducing transfusion. *Semin Perinatol* 36(4):232–243, 2012.

This review focuses on nonpharmacological approaches to the prevention and treatment of neonatal anemia, particularly in preterm neonates, including promising blood conservation strategies and techniques.

318. Committee on Obstetric Practice, American College of Obstetricians and Gynecologists: Committee Opinion No. 543: Timing of umbilical cord clamping after birth. *Obstet Gynecol* 120(6):1522–1526, 2012.

Optimal timing for umbilical cord clamping after birth is controversial. Evidence to support delayed umbilical cord clamping in preterm infants is presented, as is the lack of evidence to support delayed cord clamping in term infants.

326. Sarkar S, Rosenkrantz TS: Neonatal polycythemia and hyperviscosity. *Semin Fetal Neonatal Med* 13(4):248–255, 2008.

Neonatal polycythemia and hyperviscosity are defined and associated clinical and laboratory manifestations reviewed. Controversies in diagnosis and treatment are discussed.

CONCLUSIONS

HISTORICAL ASPECTS

Whereas many serious complications of pregnancy were well known in antiquity, maternofetal blood group incompatibility was recognized more recently. Against the high perinatal mortality prevailing until the mid-twentieth century, deaths from hemolytic disease were of little statistical significance, even though about half of the affected babies died.

In 1932 Diamond and coworkers deduced the connection between “congenital anemia,” icterus gravis, and hydrops fetalis, and coined the term *erythroblastosis fetalis* for the disease characterized by hemolytic anemia, intramedullary and extramedullary erythropoiesis, and hepatosplenomegaly.[1] Darrow correctly speculated in 1938 that the disease was caused by maternal antibodies to fetal antigens developed as a result of transplacental fetomaternal hemorrhage (FMH).[2]

In 1939 Levine and Stetson linked a woman’s severe transfusion reaction to her husband’s blood with her recent delivery of a hydropic stillborn infant.[3] She was found to have an antibody that agglutinated her husband’s red blood cells (RBCs). Levine postulated that she had become sensitized to an antigen that the fetus had inherited from its father.

In 1940 Landsteiner and Wiener[4] proposed the identity of the antigen by generating antibodies to rhesus monkey RBCs in guinea pigs and rabbits. The antisera agglutinated RBCs from 85% of white people. These people were designated rhesus (Rh) positive. The 15% whose RBCs were not agglutinated were rhesus (Rh) negative.

Subsequent years saw rapid and dramatic progress, including the development of the Coombs test.[5] This test uses anti–human immunoglobulin G (IgG) antibodies to agglutinate IgG-labeled RBCs and remains important in the detection and management of hemolytic disease of the fetus and newborn (HDFN). Chown reported in 1954[6] that mothers could be sensitized by a transplacental hemorrhage of fetal blood, although until crossmatching for Rh groups became routine, transfusion for postpartum hemorrhage and other indications also contributed to the incidence of the disease. Chown’s observation and the subsequent recognition that most sensitizing FMHs occurred at delivery, explaining why Rh HDFN was

mainly a disease of multipara, paved the way for development of immunoprophylaxis. Since the late 1960s RhD immunoglobulin has been available to treat RhD-negative mothers of RhD-positive infants at delivery to prevent Rh HDFN.

For many problems of pregnancy, obscurity of the pathophysiology often led to management that, until recently, was symptomatic at best. In contrast, with hemolytic disease the genetic predilection, molecular mechanism, and rationale for treatment were rapidly deduced, which led to remarkable success in preventing the disease and mitigating its effects. Indeed, the history of the prevention and management of RhD HDFN includes a number of pivotal discoveries that have influenced the management of other diseases. These breakthroughs include exchange transfusion for neonatal treatment, development of screening programs for maternal blood group antibodies, strategies for managing early delivery to optimize neonatal outcomes, the use of amniocentesis for fetal diagnosis, the first example of intrauterine fetal treatment, the development of one of the earliest and most successful forms of immunoprophylaxis using human antibodies, and the noninvasive prediction of fetal RHD type using DNA from maternal blood. Subsequently, many of the successes of fetal and neonatal treatment of Rh HDFN have been extrapolated to HDFN caused by other blood group antibodies and other problems of pregnancy.

Advances in molecular biology and biochemistry allowed the identification of the Rh polypeptides in 1982 and the *RH* genes in 1991. These discoveries amended previous suggested models to explain inheritance, although like many disorders that were once thought to have been genetically simple and phenotypically diverse, the diversity of Rh genotype/phenotype relationships is much greater than once imagined.

THE Rh BLOOD GROUP SYSTEM

Biochemistry and Molecular Genetics

Although the incidence of Rh HDFN has declined and the incidence of HDFN caused by other alloantibodies has increased, the Rh blood group system remains the most common cause of HDFN (particularly severe HDFN), especially in white persons, for whom approximately one in seven conceptions involves an Rh-negative woman and an Rh-positive man. Individuals are classed as Rh positive or negative based on expression of the major D antigen on their RBCs; however, more than 50 other Rh antigens have been identified, of which the most commonly recognized in clinical practice are those designated D, C, c, E, and e. The Rh blood group system is the most complex blood group system in humans.[7,8]

After the landmark descriptions of the RhD protein in 1982,[9,10] the non-D[11,12] and D complementary DNAs (cDNAs) and genes were cloned in the early 1990s.[13,14] In most individuals the Rh blood group loci are the products of two very similar genes, one of which encodes the polypeptide that carries the Rh CcEe epitopes in combinations (Ce, ce, cE, or CE); the other encodes the RhD antigen polypeptide (Table 3-1).[8,15-17] The two genes are separated by only 30 kb (including the small *SMP1* gene) and are organized in opposite orientation on chromosome bands 1p36.1-p34.3.[18] They share a very similar 10-exon structure, and their intronic sequences are also highly conserved. Their sequence identity strongly suggests that they evolved by duplication of an ancestral gene approximately 8 million years ago.[19] Worldwide, the Rh blood group system displays considerable polymorphism. A wide variety of both small and large mutations (including gene deletion and recombination to form hybrid *RHD-RHCE* products) and the effects of other modifying genes account for the diverse common and rare Rh phenotypes.[18,20] Although some genotypic and phenotypic variants are confined to a single family, for others the incidence in various gene pools is much higher or unknown. This diversity mandates caution in the use of DNA-based clinical diagnostic approaches, especially when these approaches are applied to populations other than the ones in which they were piloted, but these techniques may open the door for future individualization of prevention and therapy.[21]

It has been well established for decades that no d antigen exists. RhD negativity is defined as the absence of RhD antigen, and its incidence is highest in the Basque population.[22] It has been suggested that peripatetic Basque traders and fishermen (or their ancestors) may have spread this genotype to other populations, which explains its higher prevalence in those of European ancestry (Table 3-2). In European-descended populations in which RhD negativity is relatively common, most RhD-negative individuals are homozygous for an *RHD* gene deletion.[20,21] This mutation appears to have arisen because two highly

*The predominant reasons for failure to express RHD vary by racial group. RHD deletions predominate in whites, but other variants, such as partial deletions and RHD-RHCE recombinations, are more common in other populations.

†Rh negativity is more common in Indo-Asians.

homologous sequences (1463 bp “rhesus boxes”) flank the *RHD* gene and provide the opportunity for unequal crossing over.[23] However, although RhD negativity is less common among them, other mechanisms for D negativity appear more commonly in other populations, such as those of African, Chinese, or Japanese ancestry.[24-26] These alternative mechanisms include partial deletion, recombination between *RHD* and *RHCE* genes, and point mutation. An Rh allele that comprises a pseudogene (*RHDψ*) is prevalent among RhD-negative people of African ancestry, including approximately 66% in South Africa and about one in five RhD-negative African Americans.[26,27] *RHDψ* is not expressed because of two inactivating mutations. Singleton found that 15% of RhD-negative black South Africans carry a hybrid *RHD-CE-D* that also encodes an altered C antigen.[26]

The molecular basis of the RhD-positive phenotype is also intricate. Studies using site-directed mutagenesis, naturally occurring variants of *RHD*, and monoclonal antibodies or molecular modelling indicate that the RhD antigen is composed of at least 40 different but overlapping epitopes,[18,28-31] some of which are missing in individuals who express partial D antigenicity. The *RHD* and *RHCE* gene products are unique among blood group antigens in being nonglycosylated, palmitoylated integral membrane proteins (Fig. 3-1). Their expression is confined to erythroid cells, whereas many other blood group antigens are present in many tissues.

The RhD and RhCE antigens are found in association with a glycoprotein, formerly known as RH50 glycoprotein and now designated Rh-associated glycoprotein (RhAG). *RHAG* shares about one third homology with *RHD* and *CE*; however, it maps to 6p21.1-p11. The Rh complex comprises multimers of RhD or CE subunits with RhAg.[32]

Cartron[7] and Cartron and Colin[16] have reviewed the Rh deficiency states. Rare individuals with the Rh deficiency syndrome (Rh$_{\text{null}}$) lack expression of all or virtually all RhD, C/c, and E/e antigens. This recessive condition can result (in RhD-negative individuals) from homozygous silent mutations in the *RHCE* gene that appear to reduce cell surface expression of RhAG (“amorph type”). Homozygotes for mutations that prevent expression of RhAG have the more common “regulator type” or the Rh$_{\text{mod}}$ phenotype. Despite normal transcription of RH genes, the proteins are not found at the cell surface.[33]

The functional significance of the Rh complex is indicated by the fact that Rh-deficient individuals have spherocytosis, stomatocytosis, and chronic hemolysis of varying severity. Their RBCs have altered ion transport and membrane composition and are partly or completely deficient in certain other membrane proteins including RhAG, CD47, LW (Landsteiner-Wiener glycoprotein, or intracellular adhesion molecule 4 [ICAM-4]), GPB (glycophorin B, which confers the Ss blood group), and Duffy Fy5 (Duffy antigen receptor for chemokines). These deficiencies suggest that Rh proteins form complexes with RhAG and other proteins and that the complexes fail to form if components are missing (see Chapter 15).[7,33] There is also strong evidence for an interaction with the anion-exchange protein (band 3) and linkage of the Rh complex to the spectrin-based RBC membrane skeleton, thus indicating a role in maintaining the biconcave disc shape of RBCs (see Fig. 15-6 in Chapter 15).[34] Failure of this association may explain some of the dysfunction of Rh-deficient cells. However, many details of when, how, and why the Rh complexes form remain to be explained.

In contrast to the common Rh-negative and very rare Rh deficiency states, weak and partial D phenotypes are fairly common (e.g., 0.2% to 1% of populations of European ancestry) and are caused by *RHD* coding region alterations that affect the number and antibody binding characteristics of RhD sites per cell. The term “partial D” has been used to describe RBCs that react with some monoclonal anti-D antibodies and not others, and their RhD proteins typically have one or more amino acid

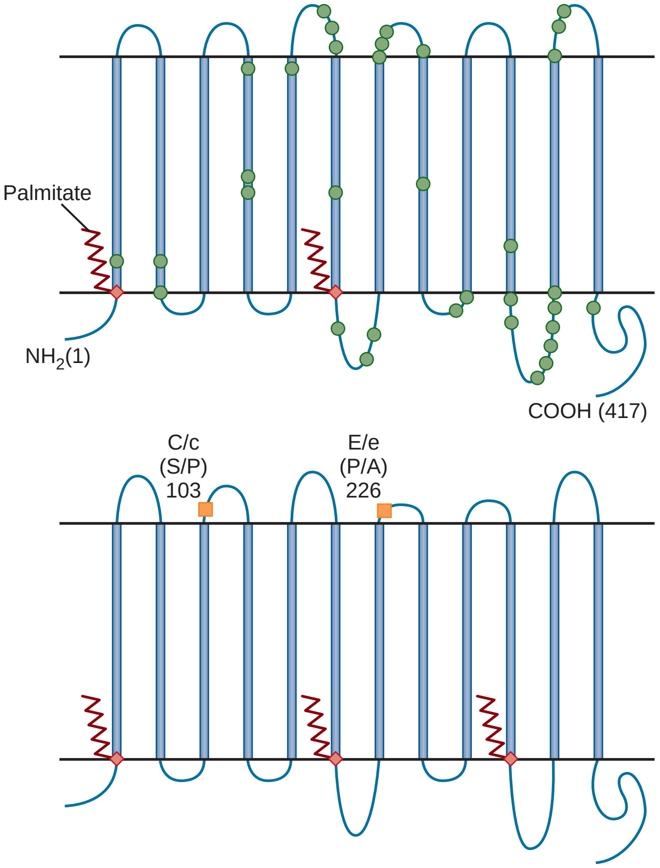

Figure 3-1 Diagram of the Rh peptides: RhD *(top)* and RhCE *(bottom)*, inserted in the cell membrane *(parallel horizontal lines)*. The amino acid sequence of both proteins predicts 12 transmembrane domains. Neither is glycosylated, but RhD has two sites of palmitoylation *(zigzag lines)*, and RhCE has three. Approximate positions of D-specific amino acids are marked with *open circles*. The predicted position of most of them is in transmembrane and cytoplasmic domains. E/e specificity appears to be conferred by a single amino acid substitution (P226A) encoded by exon 5 of the *RHCE* gene and C/c specificity by the S103P substitution encoded by exon 2. Four other amino acid differences are also associated with C/c polymorphism but do not appear to affect antigen characteristics: C16W encoded by exon 1 and I60L, S68N, and S103P all encoded by exon 2 of the RhCE gene.[8]

substitutions on or near the RBC surface, or consist of RhD-RhCE hybrids. In contrast, "weak D" has been used for RBCs with markedly reduced numbers of antigenic sites and in which one or more amino acid substitutions are found in regions that are presumed to be in or below the membrane and may interfere with assembly of Rh complexes.[35] Most individuals with weak D, especially those with types 1, 2, and 3, do not make anti-D. However, it has been recognized that there is overlap in, and some imprecision in allocation of, these phenotypes, and the terms "aberrant D" or "D variant" have been proposed as collective terms for these plus the (very weak) DEL phenotype (Table 3-3).[35]

Because of variable antigenic potential and the potential to form antibodies to RhD, certain weak and partial D phenotypes are significant in transfusion therapy and pregnancy. Some individuals are considered RhD-negative in pregnancy and as transfusion recipients (eligible for anti-RhD immunoprophylaxis and Rh-negative blood) but Rh-positive as blood donors.[35] For example, if some blood donors with aberrant, or variant, D are regarded as D negative, their blood can cause alloimmunization of D-negative recipients. On some occasions, women with D variants (especially partial D VI) develop anti-D antibodies capable of causing severe HDFN if they carry a D-positive child, or D-negative women can develop antibodies if their babies have some types of aberrant, or variant, D.[35] Some partial D phenotypes are also associated with distinct antigens.

The C antigen is most common in southeast Asia, parts of South America, and the southern tip of Greenland, whereas the E antigen occurs most often in populations indigenous to parts of South America and Alaska.[22] The genetics underlying RhCc/Ee phenotypes also display more subtle variation than was once envisaged, and weak, partial, and variant antigen phenotypes have also been recognized. Internet databases are a good source of up-to-date information about the phenotype/genotype relationships for RhD and RhCE.[36,37]

RhD ALLOIMMUNIZATION

HDFN is a disease of the fetus caused by a maternal response to pregnancy. As such, the pathogenesis can be

TABLE 3-3 Examples of Variant Rh Phenotypes for Which a Corresponding Genotype Has Been Described, Illustrating the Diversity of the RHD Genotype

Category	Phenotype	Typical Mutations
Partial D	D^{II} to D^{VII} and others	Variety of point mutations and RHD-RHCE hybrids
Weak D	Weak D (D^u) types 1-16	Variety of point mutations leading to amino acid substitutions in transmembrane or cytoplasmic domains
D negative (silent D or d)	D negative	Variety of mechanisms: RHD complete or partial deletion, CE hybrids, point mutations; some prevent transcription, but all prevent expression at the cell surface
CE variants	RN, E^{I-III}, VN, CX, C^W, etc.	Variety of hybrids and point mutations
CE silent	D.., D-, and various others	Mostly RHD-RHCE hybrids
Rh deficiency states (no D or CE expression)	D_{null} amorph $D_{null\ reg}$, $D_{null\ mod}$	RHCE silent genes plus RHD deletion RHAG mutations that prevent expression

considered in three stages: maternal alloimmunization, antibody transfer to the fetus, and fetal response.

Maternal Rh Sensitization

Maternal sensitization to Rh antigens can occur as a result of exposure to antigenically dissimilar fetal RBCs during pregnancy, as a result of therapeutic transfusion, or occasionally as a result of needle sharing.[38,39] In high-resource countries, transfusion rarely causes RhD sensititization because compatibility testing for RhD antigen has been a routine practice for several decades. However, it accounts for a high proportion of sensitization to other blood group antigens, including RhCE, and among those with RhD and RhCE variants. Furthermore, the need for emergency transfusion of Rh-positive blood to Rh-negative women is likely to remain a cause of sensitization to RhD in locations where the Rh-negative phenotype is rare and Rh-negative blood is scarce.

Exposure to fetal antigens remains the most common cause of maternal antibodies to RhD. Although Chown first described maternal Rh immunization that occurred as a result of FMH, the test of Kleihauer and associates in 1957[40] was needed to show the incidence, size, and timing of these events and to show that most maternal Rh sensitization occurs this way.[41] The test, which depends on the resistance of fetal hemoglobin (HbF) to acid elution (Fig. 3-2), can detect 1 fetal RBC in 200,000 adult RBCs, corresponding to a fraction of a milliliter in the circulating maternal blood volume. However, acid elution studies must be interpreted with some caution because of rapid destruction of fetal cells when ABO incompatibility exists and natural variation and pregnancy-induced increases in expression of HbF among adults. Using flow cytometric techniques and DNA amplification of fetal sequences, researchers have subsequently confirmed that some fetal cells can be detected in maternal blood during all trimesters of most pregnancies.[42,43] Because the strategies for detection vary among studies, there are inaccuracies of the Kleihauer-Betke test and there are uncertainties about the persistence of fetal cells in the maternal circulation, the volume and timing of this transplacental passage of fetal cells remain unclear.[44] However, most of these "hemorrhages" are likely to be small in volume. Delivery is the time of greatest risk for FMH and larger hemorrhages, especially when complications of delivery of the fetus or placenta occur.[42]

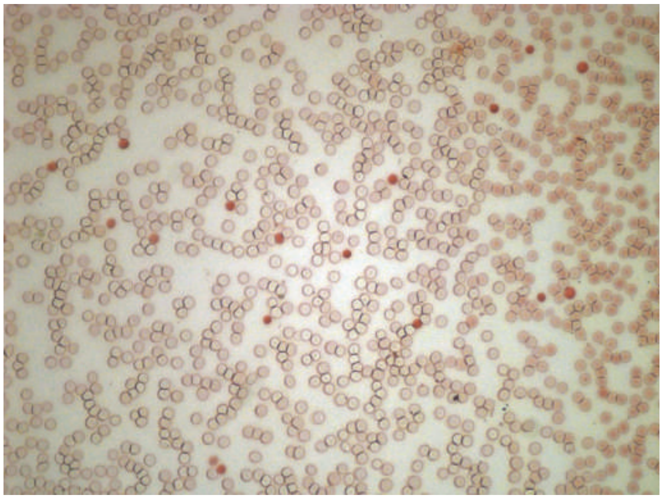

Figure 3-2 Acid elution technique of Kleihauer. Fetal red blood cells stain with eosin and appear dark. Adult red blood cells do not stain and appear as ghosts.

Larger FMHs are uncommon; the amount of fetal blood has been estimated to exceed 2.5 mL in fewer than 1% of gestations and is greater than 30 mL in fewer than 0.25%.[42] However, certain obstetric situations increase the risk of significant FMH; these include antepartum hemorrhage, placental abruption, preeclampsia, external cephalic version, cesarean section, and manual removal of the placenta.[44] Abdominal trauma and placental vascular malformations are additional but uncommon causes. FMH occurs after early-gestation chorionic villus sampling (CVS)[45] and after amniocentesis,[46,47] although the risk of maternal sensitization after amniocentesis is typically higher, perhaps because CVS is usually performed in earlier gestation when there is lower expression of fetal blood group antigens. The level of risk of sensitization as a result of first trimester pregnancy loss is also uncertain and in the case of spontaneous miscarriage will depend on whether an embryo with circulating blood ever formed, but surgical evacuation of the uterus is thought to present a greater risk of sensitization than medically induced or spontaneous evacuation.[48] The Rh antigen may be expressed by approximately 38 days after conception,[49] early enough in gestation for early CVS or pregnancy loss to present a potential risk.

All studies have focused on fetal cells in the maternal bloodstream, but the responses to submucosal, subcutaneous, or intramuscular antigen presentation differ from the responses to intravascular presentation. Therefore deposition of fetal RBCs in these sites could be more immunogenic than with the intravascular route and could account for some of the propensity for Rh sensitization after invasive procedures. If this is the case, techniques such as those recommended to minimize exposure of the fetus to maternal blood[50] might be effective in reducing risk of blood group sensitization.

The Nature of Rh Sensitization

Primary and Secondary Immune Responses

In most RhD-negative individuals, the primary immune response develops slowly. In experimental Rh immunization of male volunteers, antibody responses are typically detected at 8 to 9 weeks, although they can occur at any time from 4 weeks to 6 months. Hemolytic anemia caused by anti-RhD has been detected as early as 10 days after a massive Rh-incompatible transfusion in a previously unsensitized patient.[51] A primary, often weak immunoglobulin M (IgM) response will not affect the fetus even if it occurs before birth in a sensitizing pregnancy, because IgM anti-RhD does not cross the placenta. However, immunoglobulin G (IgG) anti-RhD production usually ensues, and if sensitization occurs in early pregnancy there is the potential for continued antigenic challenge, accounting for the rare occurrence of HDFN in the progeny of women during their first Rh-positive pregnancy.

After a primary response has been invoked, subsequent exposure to Rh-positive RBCs induces a rapid increase in anti-RhD IgG, which can cross the placenta and affect the fetus. Repeated exposures can progressively increase the antibody titer and change the characteristics (including IgG subclass distribution) of the RhD antibody, thus increasing the severity of Rh erythroblastosis in successive pregnancies.

Dose of Antigen Necessary to Produce RhD Sensitization

Experiments using injection of RhD-positive blood into RhD-negative male subjects show, not unexpectedly, that the likelihood of Rh sensitization depends on both dose and repetition of exposure to the antigen.[52] A proportion of individuals are anergic to RhD regardless of dose and repetition of exposure ("nonresponders").[52]

Studies during and immediately after pregnancy using the Kleihauer technique indicated that if the volume of FMH is always less than 0.1 mL of RBCs, the prevalence of RhD sensitization detectable up to 6 months after delivery was 3%, whereas when volumes exceed 0.4 mL, the prevalence was 22%.[52,53] Nevertheless, because in 75% to 80% of pregnancies the amount of the FMH is always less than 0.1 mL, it is likely that either small or undetectable FMHs or fetal cells deposited in other sites account for the majority of sensitizations. Secondary immune responses may occur after exposure to very small amounts of RhD-positive RBCs (as little as 0.03 mL).

Incidence of RhD Sensitization

RhD sensitization has decreased markedly with the introduction of RhD immunoprophylaxis. In its absence, about 16% of RhD-negative women become sensitized in their first ABO-compatible RhD-positive pregnancy. Of these, approximately one half have detectable anti-D 6 months after delivery, and in one half a rapid secondary response is seen in the next susceptible pregnancy, indicating that previous primary sensitization had occurred.[53,54] If sensitization does not occur, the risk in a second RhD-positive, ABO-compatible pregnancy is similar. By the time an RhD-negative woman has completed her fifth ABO-compatible, RhD-positive pregnancy, the probability that she will be RhD sensitized is approximately 50%.

As parity increases and the number of women capable of an RhD immune response diminishes because they have already become immunized, the proportion of the remainder whose systems mount a primary immune response decreases because of a greater residual number of nonresponders. About 25% to 30% of RhD-negative women are nonresponders, in that they do not become RhD sensitized despite having many RhD-positive pregnancies; however, some may yet become RhD sensitized if they are exposed to a very large amount of RhD-positive blood. Immunologic tolerance can be induced by several different mechanisms and can depend on the context of antigen presentation to the immune system. It is not known which mechanisms of tolerance predominate in nonresponding RhD-negative women.

ABO incompatibility provides partial protection against RhD sensitization. Without anti-RhD immunoprophylaxis, it has been estimated that in white persons blood group A incompatibility between mother and fetus reduces the risk of RhD sensitization by 90% and group B by 55%.[55] Bowman[54] suggested that this partial protection is due to rapid intravascular hemolysis of the ABO-incompatible, RhD-positive RBCs, with sequestration of RhD-positive cells in the stroma in the liver (an organ with poor antibody-forming potential) rather than in the spleen (the site of RBC sequestration when extravascular RBC destruction occurs). However, it is not clear whether the immune system remains naïve with respect to the RhD antigens or tolerance is induced in these instances. Although ABO incompatibility provides substantial protection against the primary RhD immune response, it provides no protection against the secondary RhD immune response[56] and should not influence management of an already affected pregnancy. Maternal HLA type does not have any consistent effect on risk of sensitization, although it may affect antibody titre and severity of HDFN.[57,58]

Other factors that influence the likelihood and severity of sensitization include fetal gender (male to female, 1.44-1.74 to 1) and fetal red cell phenotype, which affects the number and antigenicity of RhD antigen sites on fetal RBCs. For example, R1r (CDe/cde) cells, with only 9900 to 14,400 D antigen sites per cell, are less immunogenic than R2r (cDE/cde) cells, which have 14,000 to 16,000 sites.[55,59] The possibility that some RhD-negative women are exposed to RhD during their own fetal life (the so-called grandmother theory) has been considered, but the evidence from a case-control study is against it.[60] Nevertheless, convincing evidence of maternal-to-fetal hemorrhage has been found in other circumstances, and these events could explain the occasional presence of RhD antibodies in RhD-negative men who have never had a transfusion.

RhD sensitization during pregnancy occurs in about 1.5% of susceptible pregnancies.[61] The proportion of all occurrences of RhD sensitization that are attributable to antenatal sensitization now varies among studies, depending on the application of antenatal immunoprophylaxis.

In summary, some general rules apply to RhD HDFN. The probability of incompatible pregnancies is predictable from Hardy-Weinberg genetic principles, but the impact of HDFN on a population will also depend on typical family size and on careful management of obstetric complications.[62] The risk should be low when good blood bank procedures, parsimonious approaches to blood transfusion, effective screening of pregnant women, and evidence-based administration of RhD immunoprophylaxis are applied. The disease should be uncommon or mild in a woman's first incompatible pregnancy, and 50% of the infants of heterozygous fathers and sensitized mothers should be safe. However, the striking feature of pregnancies in severely isoimmunized women is their clinical variability. Because these women have often become sensitized despite the predictions of conventional wisdom, their care requires astute and conscientious management to ensure satisfactory outcomes.[56]

Prevention of Rh Sensitization

The background to the prevention of RhD sensitization lies in the experiments of Emil von Dungern at the beginning of the twentieth century.[63] He showed that serum from rabbits that had previously been injected with ox cells prevented the development of antibodies to ox cells in a second group of rabbits. The partial protective effect of ABO incompatibility also suggested that antibody-mediated destruction of fetal RBCs could prevent maternal RhD sensitization. Because anti-RhD immunoglobulin was strikingly successful in preventing sensitization in males,[41,64] clinical trials were then undertaken in which RhD-negative, unsensitized women were given anti-D intramuscularly after delivery of an RhD-positive infant.[65-67] The licensing of RhD immunoglobulin in 1968 profoundly influenced the prevalence of Rh sensitization. Despite its success, the exact mechanism of action of prophylactic RhD immunoglobulin is not yet fully elucidated.[68]

The level of evidence for the use of postpartum RhD immunoglobulin is high. A systematic review collated data from the six eligible trials involving more than 10,000 women that compared postpartum RhD immunoglobulin with no treatment or placebo.[69] The conclusion was that RhD immunoglobulin strikingly lowered the incidence of RhD alloimmunization 6 months after birth (relative risk 0.04, 95% confidence interval 0.02 to 0.06) and in a subsequent pregnancy (relative risk 0.12, 95% confidence interval 0.07 to 0.23). These benefits were seen regardless of the ABO status of the mother and baby when RhD immnoglobulin was given within 72 hours of birth. Higher doses (up to 200 μg) were more effective than lower doses (up to 50 μg) in preventing RhD alloimmunization in a subsequent pregnancy. The usual dose after full-term delivery in the United States is 300 μg (1500 International Units),[70,71] which will effectively suppress the immunizing potential of approximately 17 mL of RhD RBCs (approximately 30 mL of fetal blood),[72] although other guidelines recommend lower standard doses.[73,74,75,76] Routine assessment of the size of FMH and subsequent titration of RhD immunoglobulin dose is recommended[44,70,73,75,77] because although larger volume FMH is uncommon, it is not reliably predicted by clinical history. Postpartum prophylaxis is recommended whenever an RhD-positive infant is born to an unsensitized RhD-negative mother. RhD immunoglobulin is also recommended if the infant is positive for DVI or weak D.[70,77-79] After postnatal immunoprophylaxis, the risk of RhD alloimmunization is between 1% and 2%. Administration of 100 μg (500 IU) of RhD immunoglobulin at 28 and 34 weeks' gestation to women in their first pregnancy can reduce this risk to less than approximately 0.2%.[80] Most current guidelines therefore recommend routine administration of RhD immunoglobulin at doses of 250 to 300 μg (1250-1500 IU) at about 28 weeks or 100 to 125 μg (500-750 IU) at 28 and 34 weeks' gestation to all RhD-negative pregnant women.[81]

Some transfusion services also recommend prophylaxis to weak D-positive women,[82] although it is not recommended in most guidelines.[78] Additional or earlier doses (depending on the timing and circumstances) for RhD-negative women who are not already sensitized and who experience trauma or who are undergoing amniocentesis, CVS, or other relevant procedures may further reduce the risk of sensitization.[71,73,74-76] There is no high-quality evidence for immunoprophylaxis after early pregnancy loss or termination,[83] but RhD immunoglobulin (typically in smaller doses) is widely recommended.[71,73,74-76]

Small amounts of the RhD immunoglobulin cross the placenta and cause a weakly positive antiglobulin test, but there are no apparent adverse effects on the infant.[84] It is important to note that after antenatal RhD immunoglobulin, results of maternal antibody screening tests done near term may be positive (albeit at low titer), but under the current guidelines these results should not preclude routine estimation of peripartum FMH and administration of postnatal immunoprophylaxis.

Approximately 1 in 400 women will have a FMH of greater than 30 mL of fetal blood at the time of delivery. Such hemorrhages are often clinically silent but can be detected by routine performance of a Kleihauer-Betke test on RhD-negative mothers of RhD-positive neonates. Prevention of RhD sensitization in the presence of such a large dose of antigen requires prompt assessment (by the Kleihauer-Betke test, preferrably confirmed by flow cytometry, which is more accurate but less widely available[85,86]) and administration of a titrated dose of RhD immunoglobulin. Pediatricians must be aware of this possibility and promptly notify their obstetric colleagues of any suspected FMH in the newborn infant of an RhD-negative mother. Assessment of the magnitude of FMH is also recommended after pregnancy complications such as antepartum hemorrhage and abdominal trauma.

Certain knowledge of RhD negativity in the biologic father of the fetus can obviate the need for antenatal immunoprophylaxis. However, this information should be established with a very high degree of certainty because of the potential for severe consequences in a future pregnancy in case of error.

Reports from numerous countries document the reduction in RhD HDFN as a result of RhD immunoglobulin. Nevertheless, there is no room for complacency because 30% to 40% of the reduction in incidence of HDFN over recent decades has been attributed to decreased family size rather than to immunoprophylaxis.[87] Chavez and colleagues[88] noted that the incidence of RhD sensitization in the United States is three times the rate predicted if RhD immunoglobulin was always applied according to guidelines issued by the American College of Obstetricians and Gynecologists. The failure of the immunoprophylaxis program to completely abolish RhD HDFN can be partly attributed to noncompliance with guidelines. In addition, recommendations for additional doses during pregnancy have led to scarcity of RhD immunoglobulin in some locations. These problems are even greater in low-resource countries.[89] Giving booster doses to donors, using carefully screened RhD-positive RBCs, has been a necessity as the number of suitable sensitized donors decreases, but this practice requires extreme care to protect both the donor and eventual recipients. The distribution of the RhD-negative phenotype may increase as a result of migration. As with use of any blood product, issues of safety cannot be disregarded.[90] All these forces threaten the supply of RhD immunoglobulin. Recombinant monoclonal or polyclonal preparations—which could, in principle, replace the current polyclonal RhD immunoglobulin, thereby resolving problems of availability and safety—have been under development in recent years. However, although monoclonal antibodies have significant diagnostic and research applications, they are not yet available for prophylaxis against sensitization.[91]

Pathogenesis of Rh Hemolytic Disease

Erythropoiesis begins in the yolk sac by 14 days' gestation, and Rh antigen is expressed by the sixth week. By 6 to 8 weeks' gestation, the liver replaces the yolk sac as the main site of RBC production. Normally, erythropoiesis then diminishes in the liver and takes place nearly entirely in the bone marrow by the late third trimester of pregnancy.[92]

Erythroblastosis is caused by maternal IgG coating of fetal RBCs, leading to their destruction. The subsequent fetal anemia stimulates erythropoiesis via the production of erythropoietin and other erythroid growth factors. When fetal marrow RBC production cannot keep up with RBC destruction, marked extramedullary erythropoiesis can be found in other organs, including the liver and in more severe cases also in the spleen, kidneys, skin, intestine, and adrenal glands. Hepatosplenomegaly is a hallmark of erythroblastosis fetalis. In the presence of erythroblastosis, immature nucleated RBCs, from normoblasts to early erythroblasts, are poured into the circulation.

SEVERITY OF Rh HEMOLYTIC DISEASE

Degrees of Severity

For purposes of audit, research, and planning of treatment, degrees of severity of HDFN have been used since the 1950s.

In general, fetuses and newborns with mild HDFN have had antibody-coated RBCs, yielding positive results on a direct antiglobulin (Coombs) test, but they have no anemia or anemia that is well-compensated for in utero and after birth and do not require exchange transfusion to prevent bilirubin toxicity. This group historically accounted for approximately one half of affected fetuses. Nearly all survive and do well without invasive treatment.

Moderately affected fetuses are at risk of neural toxicity from bilirubin if they do not receive treatment (see Chapter 4). Historically, they are a group who routinely underwent exchange transfusion after birth. They are likely to have some signs of anemia in utero and ex utero but are not significantly acidotic or hydropic. Peripheral blood typically shows polychromasia, anisocytosis, and reticulocytosis, although these can be suppressed by intrauterine treatment (Fig. 3-3). Maternal clearance copes with the products of hemolysis, and the fetus is usually born in good condition at or near term. This category historically represented approximately one third of fetuses. Moderately affected neonates do require vigilant neonatal management, including intensive phototherapy or exchange transfusion to manage jaundice (Fig. 3-4).

Severely affected fetuses have hydrops or hydrops is impending, and they would die before, during, or after birth unless managed intensively. Untreated, hydrops develops in half between 18 and 34 weeks' gestation and the other half between 34 and 40 weeks' gestation.

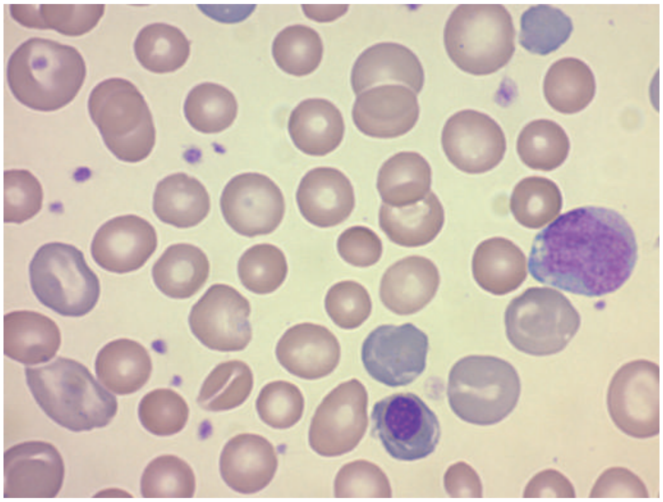

Figure 3-3 Neonatal blood sample of baby with severe Rh erythroblastosis fetalis who required an exchange transfusion at about 16 hours of age for progressive anemia with acidosis and rapidly rising bilirubin. Note the spherocytes, a promyelocyte, a nucleated red blood cell, and polychromasia.

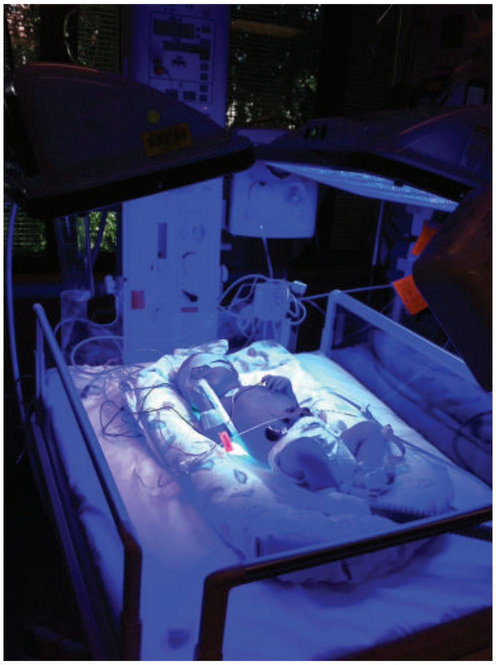

Figure 3-4 A baby receiving intensive phototherapy for anti-D hemolytic disease of the fetus and newborn. Umbilical catheters are in place for bilirubin and blood gas sampling and to undertake exchange transfusion if needed.

Polyhydramnios usually occurs early in the course of hydrops and results from decreased swallowing of amniotic fluid. Ascites is usually the first feature to develop, with severe anemia followed by skin edema and pleural and pericardial effusions. In infants with the most extreme conditions, compression hypoplasia of the lungs makes gas exchange after birth precarious.

When these categories of disease were first devised, severe fetal disease predicted severe neonatal disease. However, as fetal and neonatal management has been refined, the predictions must be updated, and the proportion of mildy and moderately affected neonates has risen. For example, some mildly anemic but not hydropic neonates who met previous criteria for exchange transfusion are now managed effectively with intensive phototherapy and would therefore be regarded as having mild rather than moderate disease. Similarly, a fetus with early development of hydrops (severe HDFN) may respond well to one or more intrauterine transfusions and therefore be born with mild neonatal disease and yet still have severe late anemia that is as much a consequence of hematopoietic suppression caused by effective intrauterine treatment as of hemolysis caused by the underlying disease. A suggested update to the working definitions that separates the criteria into epochs and includes a summary of implications for practice is given in Table 3-4.

Pathogenesis of Hydrops

Hydrops in HDFN was originally attributed to fetal heart failure, but other factors probably play a role.[93] With severe hemolysis and progressively greater extramedullary erythropoiesis, the hepatic architecture and circulation are distorted by the islets of erythropoiesis. It has been suggested that this results in portal and umbilical venous obstruction and portal hypertension. Impairment of umbilical venous return would exacerbate the fetal tissue hypoxia caused by anemia and explain the placental edema that is usually seen in severe hydrops. The placental edema, by increasing the placental barrier to gas exchange, could then impair oxygen delivery even more. The theory that liver distortion and dysfunction are at least as important as heart failure in the pathogenesis of hydrops fetalis could explain why hydrops is not always accompanied by hypervolemia or even severe anemia.[93] Support for the suggestion that portal hypertension is present is provided by ultrasound assessment of waveforms in the portal venous system.[94]

Hypoalbuminemia is a common feature, but the mechanism has not been explained. It could be caused by a greater volume of distribution for albumin or reversion to α-fetoprotein expression rather than failure of hepatic synthesis.

The mechanisms that lead to hydrops, both in anemic fetuses and in nonanemic fetuses with "nonimmune" hydrops, remain poorly understood. Various inflammatory mediators could play a role but have not been examined. Genes that are regulated by hypoxia include those for vascular endothelial growth factor and other molecules involved in capillary morphogenesis. Depending on the pattern of expression, these molecules can markedly affect capillary permeability and could also play a role.

Factors Affecting the Severity of Hemolytic Disease of the Fetus and Newborn

If a sensitized mother is pregnant with an Rh-incompatible fetus, a number of factors influence the severity of disease in the fetus. These factors include placental transfer of antibody, antibody characteristics, antigen characteristics, state of maturation of the fetal spleen, and resilience of fetal erythropoiesis.

Transfer of Antibody to the Fetus

All four IgG subclasses are transported across the placenta, via FcRn receptor–mediated endocytosis and then exocytosis.[95-97] The fetal-to-maternal ratio for total IgG is approximately 0.4 at 28 weeks' gestation and increases to 1.4 at term,[98] but fetal levels of IgG1 are close to maternal levels by 17 to 20 weeks' gestation.[99] The efficiency of placental transport of antibody may be an important factor in the severity of Rh HDFN, and reduced IgG transport can result in unexpectedly mild disease.[100]

Mechanism of Red Blood Cell Hemolysis

When anti-RBC antibodies bind complement and are present in high concentrations (as with transfusion reactions to ABO-incompatible blood in adults), RBC intravascular destruction occurs and may cause a clinically severe reaction including hemoglobinemia, shock, and disseminated intravascular coagulopathy. Products of RBC destruction are cleared predominantly by the liver.

When antibodies do not fix complement, as is typical with anti-RhD in the fetus and neonate,[101,102] the mechanisms of hemolysis are more subtle but, in the end, equally destructive. Three Fc receptor–mediated pathways have been implicated in the destruction of opsonized RBCs: direct phagocytosis, phagocytic damage leading to later lysis, and killer cell–mediated damage. When anti-RhD becomes concentrated on the membrane of RhD-positive RBCs, the RBCs adhere to macrophages and form rosettes. This occurs particularly in the red pulp of the spleen, where RBCs and macrophages come into close apposition. The phagocytic cell can then destroy the RBC or damage and deplete the membrane, causing loss of RBC deformability. If the RBC escapes being consumed by the macrophage, its membrane is damaged, and its osmotic fragility and likelihood of lysis are greater.

Antibody-dependent cellular cytotoxicity (ADCC) probably also accounts for the destruction of some RBCs.[103] Large granular "K cells" (natural killer lymphocytes) or myeloid cells (polymorphonuclear leukocytes and monocytes) bind antibody-labeled cells and release lysosomal enzymes and perforin, causing lysis.

Hemolysis also requires a competent system of phagocytic cells in the fetus. The clinical manifestations of the disease suggest that their maturation is sufficient as early as the middle of the second trimester.

Antibody Specificity and Severity of Hemolytic Disease

Antigen characteristics, including details of antibody distribution, density, and structure, all affect risk for HDFN; these have been reviewed by Hadley.[104] Antibodies with

TABLE 3-4 Degrees of Severity of Rh Hemolytic Disease of the Fetus and Newborn

Severity	Mild	Moderate	Severe
In Fetus			
Historical proportion of Rh HDFN before intrauterine therapy was available	~50%	25%-30%	20%-25%
Likely history in previous siblings	No exchange transfusion	Exchange transfusion unless in utero treatment	Death unless in utero treatment
Likely maternal anti-D titer	<1:64	>1:64	>1:64
Ultrasound abnormalities	None	Altered patterns of flow in fetal vessels	Signs of severe anemia (see Table 3-5), which may lead to hydrops, portal hypertension, ascites and other effusions, polyhydramnios
In Neonate			
Clinical condition at birth	Normal	Mildly or moderately ill	Hydrops
Hemoglobin at birth	No anemia	Mild, or moderate anemia; Hg >0.6 MoM for gestation	Severe, symptomatic anemia Hg <0.6 MoM
Hemoglobin nadir	Transfusion not needed	At risk for symptomic anemia	Risk of death unless transfusion
Bilirubin cord	<3.5 mg/dL (≈70 μmol/L)	>3.5 mg/dL (≈70 μmol/L)	>3.5 mg/dL (≈70 μmol/L)
Bilirubin peak	Term: <20 mg/dL (≈380 μmol/L) Premature: lower levels depending on prematurity	Term: >20 mg/dL (≈380 μmol/L) Premature: lower levels depending on prematurity	Rate of RBC destruction depends on (low) hemoglobin B; peak bilirubin is variable, toxicity increased
Phototherapy	If bilirubin increases faster than 0.4-0.5 mg/dL/hr; lower threshold for premature infants	If bilirubin increases faster than 0.4-0.5 mg/dL/hr; lower threshold for premature infants	Immediate, intensive, pending measurement of bilirubin increase
"Early" exchange	No	If rate of increase of bilirubin >0.8-1 mg/dL/hr despite several hours of intensive phototherapy; lower threshold for premature infants	If rate of increase of bilirubin >0.8-1 mg/dL/hr despite several hours of intensive phototherapy; lower threshold for premature infants
"Late" exchange	If bilirubin > exchange level	If bilirubin ≥ exchange level	If bilirubin ≥ exchange level
Heme oxygenase inhibition	Unnecessary; number needed to treat to avoid exchange will be high	In context of well-designed clinical trials	In clinical trial to avert late exchange; unlikely to allow avoidance of early exchange
Intravenous immunoglobulin	Unnecessary; number needed to treat to avoid exchange will be high	Evidence from high-quality trials to date does not support; therefore only in context of further well-designed randomized trials	Evidence from high-quality trials to date does not support; therefore only in context of further well-designed randomized trials
Phenobarbital	No	Neonatal—no clear benefit if optimal phototherapy; may be role for antenatal treatment in context of well-designed clinical trials	Neonatal—no clear benefit if optimal phototherapy; may be role for antenatal treatment in context of well-designed clinical trials
Erythropoietin (or analogue) for late anemia	No	In context of well-designed clinical trials	In context of well-designed clinical trials

the potential to cause HDFN generally recognize antigens restricted to erythroid cells (e.g., Rh antigens) rather than those with a wider tissue distribution (e.g., A and B antigens, found on many cell types). The antigens must be expressed in the fetus and neonate. Thus antibodies to Kell and Rh antigens, which are expressed early in fetal life, cause severe HDFN, whereas antibodies to Lewis antigens, which are not synthesized in erythrocyte progenitors, never cause HDFN. The circulating glycosphingolipids carrying the antigenic Le^a or Le^b epitopes generally only adsorb to the erythrocyte membrane during postnatal life. Lewis antibodies are also usually

IgM. Lewis is the only human blood group system that has never been reported to cause HDFN of any severity.

Antigen density is also an important factor. Within the Rh system, even in the presence of high maternal anti-RhD titers, fetuses with weak RhD phenotypes are unlikely to be severely affected.[79] As might be expected, homozygotes for *RHD* appear to have higher RhD antigen density than heterozygotes,[59] although this is only potentially relevant in unusual situations such as ovum donation, because otherwise RhD positive infants of negative mothers are obligate heterozygotes. *RHCE* genotype also affects RhD antigen density, and in particular there seems to be higher expression of D where CE is deleted or underexpressed.[105,106] The density of several other antigens, including A and B and the Lutheran antigens,[107] is developmentally regulated, and antigen density on immature RBCs limits the severity of hemolysis. Antigen structure may also play a role, with some antigens being more capable of promoting recognition of RBCs by phagocytic cells.

Antibody characteristics also play a role in determining the severity of HDFN. IgG subclasses bind different classes of Fc receptors, although it has not yet been established conclusively which receptors are involved in RBC destruction in vivo. Fc receptor polymorphisms that bind IgG more avidly (and may play a role in ABO HDFN[108]) may yet be found to account for some of the heterogeneity of Rh HDFN.[104]

Whereas anti-A and anti-B antibodies are predominantly IgG2, IgG1 and IgG3 anti-D antibodies tend to predominate in Rh-sensitized women.[109-112] The different IgG subclasses are often present in combination.

The capacity of RBC-bound IgG3 antibodies to bind to Fc receptors of monocytes is greater than that of IgG1 antibodies. Threshold levels of antibody binding for rosette formation in vitro are approximately 1000 IgG3 or 2000 IgG1 molecules per RBC.[113] Both can promote phagocytosis, but their relative potencies depend on circumstances. IgG3 usually causes more efficient lysis by monocytes than does IgG1.[113-115] Clearance of Rh-positive RBCs is caused by fewer molecules of IgG3 anti-D than of IgG1 anti-D.[116] However, there is some evidence that IgG1 is more important in the pathogenesis of severe HDFN.[117]

Human leukocyte antigen (HLA) antibodies have been found in the sera of some women who have infants with mild HDN despite high antibody levels. The HLA antibodies may block antibody-antigen interactions on the macrophage membrane.[104]

ANTIBODY DETECTION

ABO and RhD typing plus antibody screening is recommended at the first prenatal visit in all pregnancies, including visits for elective abortion. A history of prior pregnancies and blood transfusions should also be taken. If the blood group is D-negative or weak D, another antibody screening is recommended at 24 to 28 weeks' gestation, before administration of anti-D immunoprophylaxis. If an alloantibody is detected at a low titer, screening is usually repeated at regular intervals to detect any increase. There are a variety of methods for assessing maternal antibodies, some that are better suited for screening methods and some that are more useful for predicting severity of disease.[104]

Manual Methods

Coombs serum is an anti–human globulin produced by immunizing another species.[5] Rh-positive RBCs are incubated with the serum sample that is being tested for the presence of anti-RhD. If anti-RhD is present in the sample, it adheres to the RhD-positive RBC membrane. The RBCs are then washed to remove nonadherent human protein and suspended in Coombs serum. If the RBCs are coated with anti-RhD, they are agglutinated by the antibodies to human immunoglobulin (positive test result). The reciprocal of the highest dilution of maternal serum that produces agglutination is the indirect antiglobulin titer.

Incubation of RBCs with enzymes such as papain, trypsin, and bromelin reduces the electrical potential of the RBC membranes, allowing agglutination of Rh-positive cells by IgG anti-D even in saline. Enzyme screening methods are the most sensitive manual techniques available for detecting Rh sensitization, but they detect many antibodies that have no clinical significance.[118]

These manual methods have the advantages of sensitivity and flexibility, but the correlation between antibody titer and disease severity is poor.

Automated Analysis

Autoanalyzer methods have been developed and refined for more efficient and reproducible detection and quantitation of Rh and other antibodies.[119] Autoanalyzer techniques are very sensitive, and the finding of an Rh antibody detected only by an autoanalyzer method does not necessarily indicate the presence of HDFN or even true sensitization, especially if the titer is very low and stable. However, rising titers indicate the need for urgent assessment of the fetus.

PREDICTION OF FETAL HEMOLYTIC DISEASE

Once sensitization is detected, subsequent investigative measures are required. To refine the estimation of risk, one or more of the following may need to be considered.

Fetal blood type is determined by the following:

- Paternal blood typing
- Fetal blood typing

Severity of disease is predicted by the following:

- History indicating the severity of HDFN in previous infants
- Maternal antibody quantitation
- Fetal ultrasound
- Amniotic fluid spectrophotometry
- Percutaneous fetal blood sampling

Determination of Fetal Blood Type

Paternal Blood Typing

In some instances paternal blood typing can indicate that the baby has no risk for HDFN. This situation occurs if the father is Rh negative and the mother was sensitized not by his offspring but by those of a previous partner or by transfusion. If the father is predicted to be Rh negative or heterozygous, the fetus may be completely unaffected regardless of the maternal antibody titer. In predominantly white populations, approximately 56% of Rh-positive individuals are heterozygous. Because the *RHD* and *RHCE* genes are closely linked, paternal RHD zygosity can be estimated from his Rh c/C and e/E type and his race, or more accurately using molecular techniques.[20,120]

Fetal Blood Typing

Fetal Rh typing by genotyping, using DNA amplification or microarray techniques, is becoming increasingly feasible and widespread and is supplanting the need for antigen typing of fetal blood. Although the need for it can be obviated if paternal homozygosity is certain, it can be an especially important technique when paternity is uncertain or the father is heterozygous.

Molecular methods are now used routinely and with high accuracy in many locations to detect fetal *RHD*, *RHCE*, *KEL*, *DARC* (Duffy), and *SLC14A1* (Kidd) genes in free fetal DNA in maternal blood, obviating the need for chorionic villus biopsy or amniocentesis to obtain fetal DNA.[121,122] Cell-free fetal DNA, presumed to be from apoptotic syncytiotrophoblast, is now most commonly used for fetal genotyping because unlike some fetal cells found in the maternal circulation, it is cleared rapidly after delivery and therefore reflects only the current pregnancy.[123] Fetal genotyping has the potential to reduce or predict the need for assessment throughout the pregnancy, including the need for invasive tests, and to avert the need for RhD immunoglobulinduring some pregnancies. Single-cell preimplantation diagnosis has also been described.[124]

The genetic diversity of the Rh blood group system outlined in an earlier section of this chapter provides an important reminder to use caution in choosing primers that minimize false-positive and false-negative test results and to keep in mind the fact that genotype does not always obviously predict phenotype. The prevalence of *RHD-RHCE* hybrids and partially intact but functionally inert RH genes in certain populations can markedly reduce the validity of tests designed for application in predominantly white populations. The use of appropriate controls; amplification of at least two diagnostic sites, preferably checking the correlation between parents' genotype and phenotype in parallel; and performance of the tests with a good understanding of the typical genotypes in the populations for which they were developed and to which they are being applied should minimize errors.[78,122,125,126,127] The need to have a good positive control for fetal DNA to identify false-negative results is critical. The *SRY* sequence can be used if the fetus is male, but more complicated comparison of multiple fetal and parental polymorphisms in other genes may be necessary if the fetus is female. Differential methylation of the maspin gene in fetal and maternal tissues recommends it as a universal positive control.[128,129]

RHD genotyping of amniotic and chorionic cells agrees with serologic and tissue typing,[130] allowing CVS or amniocentesis to be used for typing of the fetus. However, the need to use these procedures should diminish as procedures using fetal DNA from maternal blood become more widely available. Some advantages of diagnosis using maternal blood samples are the ability to type early in pregnancy and the fact that sample acquisition neither risks harming the fetus nor increases maternal exposure to fetal antigens.

Prediction of Severity of Disease

The relative roles of methods for assessing the severity of hemolytic disease in the fetus have changed in recent years.

Pregnancy History

Although it is usually true that the severity of HDFN remains the same or increases during subsequent affected pregnancies, the disease sometimes becomes less severe. If a previous baby was hydropic, a subsequent affected fetus has a 90%, but not a 100%, chance of developing hydrops. If hydrops is going to develop, usually it does so at the same gestation or earlier, but occasionally it develops later. In a first RhD-sensitized pregnancy, with no prior history of HDFN, there is an 8% to 10% probability that hydrops will develop. If a mother has had a previous fetus with hydrops and the father is heterozygous for the offending antigen, the fetus may be negative and completely unaffected or positive and very severely affected, a dilemma that requires resolution, usually by fetal typing. Thus there are numerous situations in which the history of previous pregnancies is unreliable, although it is nevertheless worth noting.

Maternal Antibody Titers

Although antibody titrations carried out in the same laboratory by the same experienced personnel using the same methods and test cells are reproducible and do give the physician some indication of risk, their predictive value is inadequate to guide invasive fetal treatment. Use of automated analyzers provides somewhat better prediction of the severity of HDFN than manual methods do, but the two approaches have not been compared rigorously. Hadley[104] has noted that whereas many laboratories can and should undertake screening for alloantibodies, antibody quantitation is best limited to regional centers with proven reliability. Ideally, these laboratories will also have strategies for auditing the outcomes of pregnancies in which antibodies have been detected. This can lead over time to the recognition of a critical titer, below which no cases of severe disease have occurred; this allows targeting of more extensive and invasive tests to those with titers above the threshold. However, the follow-up needed is laborious, prone to ascertainment bias, and possibly a violation of patient privacy. Generally, if the obstetric history is good, low titers (≤1:16 by manual methods or <5 IU/mL [1 μg/mL] by autoanalyzer) that increase slowly or not at all are reassuring and indicate continued surveillance using antibody titers and ultrasound.

Although rising titers suggest increasing risk to the fetus, it has not been possible, even with autoanalyzer methods, to establish a titer above which the fetus must be sensitized,[131,132] and sometimes antibody levels increase significantly (but presumably nonspecifically) despite the presence of a compatible and therefore unaffected fetus. Nevertheless, in the presence of high or rising titers, fetal assessment becomes urgent.

Amniotic Fluid Spectrophotometry

Bevis[133] showed that bilirubin could be found in the amniotic fluid of infants with HDFN, and in 1961 Liley[134] plotted fetal outcomes by gestation and results of amniotic fluid spectrophotometry, thus devising a prenatal test of severity of HDFN that has only recently been surpassed as the standard method of assessing fetuses with hemolytic disease. Liley used the ΔOD_{450} reading (the deviation from linearity at 450 nm caused by the absorption spectrum of bilirubin) as a measurement of the amniotic fluid bilirubin level. Three zones of predicted severity of disease were defined (Fig. 3-5). Readings in zone I indicated either no disease or no anemia at the time of testing but reflected a 10% chance that exchange transfusion would be needed. Readings in zone II indicated moderate disease that becomes more severe as readings approach the zone III boundary. Readings falling into very high zone II or zone III indicated severe disease: hydrops was present or would develop within 7 to 10 days. When serial ΔOD_{450} measurements are taken, the overall accuracy of prediction of hemolytic disease with the amniotic fluid technique is 95%. Accuracy is higher in the third trimester than in the second trimester. Because the graphs were developed before intervention at earlier than 27 weeks' gestation was contemplated, zone boundaries in the second trimester were not defined. The Liley zone boundaries were subsequently modified by inclining them downward before 24 weeks' gestation because of the observation that ΔOD_{450} readings peak at 23 to 24 weeks' gestation in pregnancies unaffected by HDFN.[135] The division lines for Queenan's chart are lower at all gestations than those of Liley's system. Although it was suggested that Queenan's modification could overestimate severity, leading to too many interventions,[136] others concluded that a more conservative approach was appropriate as safer and more effective intervention became available.[137] Monitoring by ultrasound and selective direct fetal blood sampling has markedly reduced the need for assessment by amniocentesis. Amniocentesis may still sometimes be useful as an adjunct to ultrasound to assess severity. Increases in antibody titer occur after some amniocenteses, although the risk is reported to be lower than that after umbilical blood sampling.[46,138]

Ultrasound Assessment

The development of obstetric ultrasonography in the late 1970s was a major advance in the management of maternal blood group alloimmunization. Ultrasound allows estimation of placental and hepatic size and determination of the presence or absence of polyhydramnios, edema, ascites, and other effusions. It increased the safety

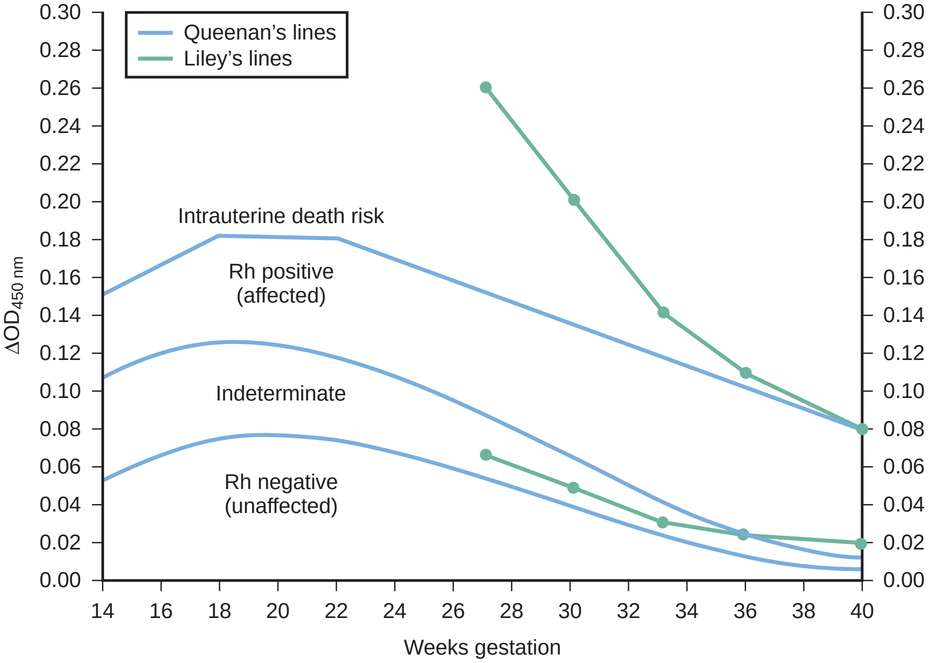

Figure 3-5 Superimposed Queenan and Liley charts of the deviation of absorbance at a wavelength of 450 nm (ΔOD_{450}) versus gestation. Liley's lines began at 27 weeks, and they were rectilinear when shown on a log-linear plot.[134] They were subsequently extrapolated back to 20 weeks.[135] Queenan's chart demonstrates that the lines should deflect downward in the early second trimester.[136] However, the division lines for Queenan's chart are lower at all gestations and may overestimate risk in some fetuses. Current practice is to use fetal cerebral velicometry instead of, or sometimes in addition to, amniotic fluid results in determining the need and timing for intrauterine treatment. *(Redrawn from Scott F, Chan FY: Assessment of the clinical usefulness of the "Queenan" chart versus the "Liley" chart in predicting severity of rhesus iso-immunization.* Prenat Diagn *18:1143-1148, 1998.)*

of amniocentesis and intraperitoneal transfusion and is essential for umbilical blood sampling and intravascular fetal transfusions.

Although ultrasound was previously said to be of little use in assessing the severity of disease until hydrops had developed, assessment of flow velocities in major fetal vessels has now been shown by several groups to be reliable for detecting significant fetal anemia. Middle cerebral artery (MCA) velocimetry is the most extensively used assessment.[139] Published reports comparing MCA peak systolic velocity (MCA-PSV) to threshold levels of fetal or neonatal hemoglobin, show some variation in prediction, but MCA-PSV above 1.5 multiples of the median (MoM) is strongly correlated with severe fetal anemia.[139] As the test becomes more widespread and reduces the need for fetal sampling, it may become more difficult for practitioners to audit outcomes and refine their judgments accordingly. Nevertheless, when skills to perform it are available, MCA velocimetry has become the method of choice for monitoring women with blood group–sensitized pregnancies and in the planning and timing of invasive fetal sampling, fetal treatment, and delivery (Table 3-5, Fig. 3-6).[139,140,141]

Percutaneous Fetal Blood Sampling

With the development of sophisticated ultrasound equipment and the availability of perinatologists skilled in its use, percutaneous fetal umbilical blood sampling became feasible in the mid-1980s.[142] This procedure allows direct diagnosis of fetal blood type, hemoglobin, and acidosis and therefore provided the "gold standard" for diagnosis of fetal anemia against which the accuracy of other assessment techniques has been assessed. The procedure does carry with it a likelihood of fetal-to-maternal hemorrhage and a small risk of fetal mortality.[138,143] Generally, it should be reserved for use when ultrasound (or amniocentesis) indicates moderately severe or severe disease with a probable need for intrauterine treatment. It is generally not indicated unless fetal treatment of severe anemia appears to be justified for continuation of the pregnancy and safe delivery. Fetal blood sampling and intrauterine blood transfusion may be possible as early as 13 weeks' gestation[144]; it usually is feasible by 16 weeks' gestation.[145] The preferred sampling site is the umbilical vein at its insertion into the placenta. For this reason the procedure is technically easier to perform if the placenta is implanted on the anterior uterine wall.

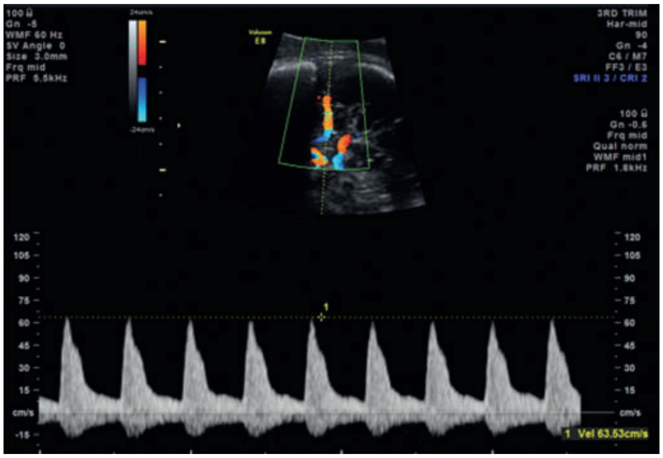

Figure 3-6 Middle cerebral artery Doppler study showing measurement of the elevated peak systolic velocity that is now the method of choice for detecting fetal anemia. Middle cerebral artery peak systolic velocity (MCA-PSV) can predict fetal anemia with sufficient accuracy to determine management, including the need for intrauterine transfusion or in the mid to late third trimester, early delivery. Fetal hemoglobin is typically measured at the start and end of intravascular transfusion to validate the prediction from MCA-PSV results. The reliability of MCA-PSV can decrease after intrauterine transfusion because of the altered rheostatic characteristics of transfused adult blood.

TABLE 3-5 Comparison of Test Characteristics for Peak Systolic Velocity in the Middle Cerebral Artery Measured via Doppler Ultrasonography and Amniotic Fluid ΔOD_{450nm} in Predicting Severe Fetal Anemia*[140]

	Sensitivity	Specificity	Accuracy
Test	Percent (95% Confidence Interval)		
MCA blood flow >1.5 MoM[245]	88 (78-94)	82 (73-89)	85 (79-90)
Amniotic fluid ΔOD_{450nm}			
Modified Liley chart—upper third of zone II or zone III[136]	76 (65-84)	77 (67-84)	76 (69-82)
Queenan chart—zone IV[135]	81 (71-88)	81 (72-88)	81 (75-86)

MoM, Multiples of the median.
*Defined as a hemoglobin level 5 SD or more below the mean for gestation.

MANAGEMENT OF MATERNAL ALLOIMMUNIZATION

Suppression of Alloimmunization

Since the mid-1940s, efforts have been made to suppress the strength of already developed maternal immune responses against fetal RBC. Administration of Rh immune globulin, of great value in preventing Rh sensitization, has been shown to be ineffective in suppressing an established antibody response, no matter how weak, once it has begun.[146]

Two measures that have potential to reduce maternal antibody levels and ameliorate hemolytic disease are (1) intensive plasma exchange[147,148] and (2) the administration of nonspecific intravenous immune serum globulin (IVIG).[149-151] With intensive plasma exchange, alloantibody levels can be lowered by as much as 75%, but they tend to rebound, at times to levels higher than they were before.[152] Vascular access becomes difficult, and IgG and albumin administration is needed. Plasma exchange may have a role in a mother with a fetus known to be susceptible to the antigen to which she is immunized and who has a prior history of severe, early HDFN, especially before 20 weeks' gestation, when the risks and technical difficulty of intrauterine transfusion are higher.[145,153,154] However, the risk-to-benefit ratio remains insufficiently high to recommend it for routine management.

High-dose IVIG administration can also be effective in the severely alloimmunized pregnant woman. The mechanism of action could include inhibition of antibody synthesis or competitive blockade of receptor-mediated transfer across the placenta or binding sites on fetal immune cells. If IVIG therapy is considered, it should be used for indications similar to those for intensive plasma exchange, beginning at 10 to 12 weeks' gestation. Ongoing assessment of fetal disease remains essential because not all fetuses respond adequately. Because of its cost, inconvenience, and side effects, its use, like that of plasmapheresis, is reserved for fetal disease that is expected to be refractory to other therapy.[154]

Fetal Treatment

Induced Early Delivery

Premature delivery of fetuses with Rh HDFN has been important in prevention of mortality since the late 1940s. With the introduction of amniotic fluid assessment in 1961, it became possible for the first time to predict which fetuses should be considered candidates for early delivery. Subsequent advances in perinatal and neonatal management of premature infants have had a major impact on survival. However, HDFN is different from many other pregnancy complications in that intrauterine treatment has been very effective in prolonging many gestations. As the effectiveness of fetal treatment has improved, particularly after the introduction of intravascular intrauterine transfusions, the need for premature delivery of infants with HDFN has diminished. Nevertheless, delivery at 36 to 37 weeks is frequently advisable, particularly in moderate and severe HDFN, to prevent the progression of anemia at late gestation, when fetal treatment often becomes impracticable and neonatal treatment presents fewer risks.[154,155] If premature delivery is required before 34 weeks' gestation, antenatal betamethasone therapy should be given to the mother according to consensus guidelines. It is probable that infants with HDFN have as much or more to gain from use of this important preparation for extrauterine life than their gestation-matched peers with other fetal conditions. Glucocorticoids are often given if intrauterine transfusion is needed (provided the fetus is of sufficient gestation, size, and condition) in case complications of the procedure lead to premature birth. The blood bank should be forewarned so that appropriate blood for exchange transfusion can be obtained if needed. A possible role for antenatal phenobarbital treatment to reduce the need for exchange transfusion of the neonate warrants investigation in randomized controlled trials.[156,157]

Intrauterine Transfusions for Fetal Hemolytic Disease

Until 1961, induced early delivery and neonatal treatment offered the only hope for infants with severe Rh HDFN, but at that time it could not be undertaken before 31 to 32 weeks' gestation without the risk of prohibitive mortality from prematurity. Hydrops develops in 8% of fetuses before 32 weeks' gestation. In 1963 the introduction of intraperitoneal fetal transfusion (IPT) by Liley[158] completely altered the prognosis for these most severely affected of all fetuses

Since the beginning of the twentieth century, it was known that RBCs placed in the peritoneal cavity are absorbed and function normally. At one time, IPT was a preferred method for giving transfusions to children with thalassemia. It was abandoned in favor of vascular transfusions because of the severe discomfort that it caused. Absorption is by way of the subdiaphragmatic lymphatic lacunae, up the right lymphatic duct, and into the venous circulation. In the fetus, breathing movements are necessary for absorption to occur.[159] In the absence of hydrops, 10% to 12% of infused RBCs are absorbed daily. Ascites does not prevent absorption per se, although the rate of absorption in its presence is less predictable and the procedure is more risky. Rupture of membranes and spontaneous labor after IPT are also risks.

Although IPT was a major advance in the management of severe erythroblastosis fetalis, it has been largely superseded by intravascular transfusion (IVT). The earliest attempts at direct IVTs, either into a fetal or placental blood vessel approached through a hysterotomy incision, were made in the mid-1960s, but outcomes were poor because complications such as premature labor almost invariably ensued.[160,161] In 1981 Rodeck and coworkers[162] reported direct fetal transfusions through a fetoscope. This method was soon superseded by percutaneous transfusion into umbilical vessels.[163-167] Under ultrasound guidance the tip of a needle is introduced into an umbilical vein, usually either at its insertion into the placenta (Fig. 3-7) or the umbilical or hepatic vein within the fetus (Fig. 3-8). Fetal blood sampling usually precedes and follows the transfusion, and confirmation that the needle tip remains in the correct position can be obtained throughout the procedure by observing altered echoes in the vessel on ultrasonography.

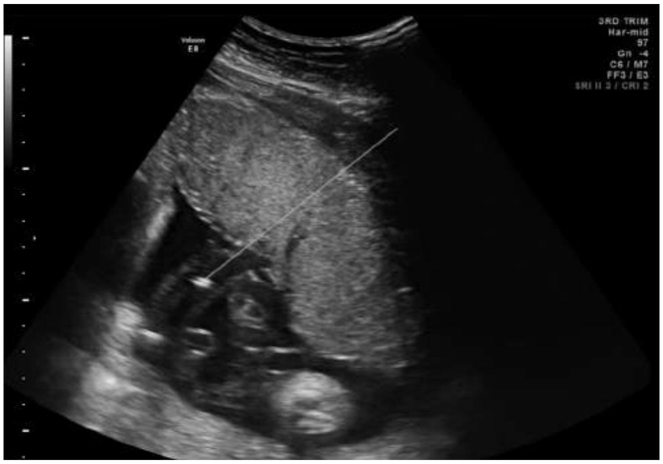

Figure 3-7 Real-time two-dimensional ultrasound view of intravascular transfusion near the insertion of the umbilicus into an anterior placenta. The path of the needle past the placenta is illustrated by the *superimposed line*.

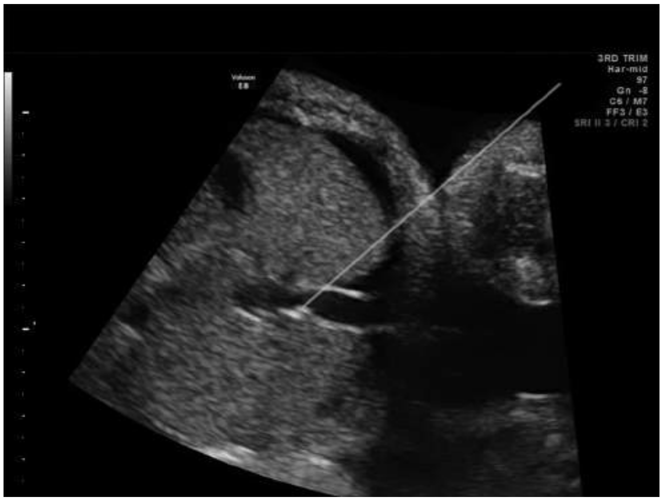

Figure 3-8 Real-time two-dimensional ultrasound view of intravascular transfusion into the intraabdominal portion of the umbilical vein, near the porta hepatis. The path of the needle past the placenta is illustrated by the *superimposed line*. This technique is preferred by some and used selectively by others when (owing to placental and fetal position) the insertion of the umbilical vein to the placenta is inaccessible. Fetal movement can result in dislodgment of the needle, but if that occurs, in some cases, the intrauterine transfusion can be completed as an intraperitoneal transfusion.

IVT offers a number of advantages compared with IPT. IVT allows direct diagnostic sampling at the onset of the procedure, to determine fetal well-being and determine volume to transfuse, and at completion to confirm success and to help predict need for subsequent intrauterine treatments.[154] For skilled practitioners the failure rate, procedure-related complication rate, and mortality rate are low, even in hydropic fetuses.[154,168,169] It allows larger transfusions than IPT and administration of platelets if needed. It is effective in correcting anemia and its immediate physiologic consequences and in reversing hydrops.[166] Survival and neonatal condition were improved so rapidly by the introduction of IVT that, just as with IPT before it, its merits have been determined by comparison with historical control data rather than with prospective randomized studies. Comparison with historical control data may fail to take into account numerous other improvements in perinatal and neonatal care since the 1970s. However, babies with more severe disease respond to IVT, and they need less invasive and intensive neonatal care afterward. Undoubtedly, if an intrauterine procedure is necessary and IVT is feasible, it is the procedure of choice. The overall survival rate of severely anemic fetuses with HDFN who are treated with IVT averages 90% to 95%.[170] Follow-up studies indicate that most survivors of both IPT and IVT have good prognoses for neurologic development and general health.[171] Umbilical and inguinal hernias are reported to occur often after IPT.[172]

Despite the great advantages of IVT, in some situations IPT remains necessary. These include the fetus that is severely afflicted early in pregnancy, at a time when the cord vein is too small for a successful venipuncture. In late pregnancy or in twin gestation, fetal size and position may preclude access to the umbilical vessels. IPT may also be used to “top-up” an incomplete IVT if needle dislodgment or other immediate complications occur.

Both IVT and IPT can expose the mother to fetal cells, raising her antibody titer and potentially worsening disease. As stated earlier, there is no benefit to giving anti-D antibody to these already sensitized mothers. In the future other methods of immunomodulation might prove beneficial to improve the safety of this aspect of treatment.

It has been recommended that both IPT and IVT be performed in centers that perform at least 20 to 30 cordocenteses and 10 to 15 transfusions annually to maintain competence and to allow adequate surveillance of outcomes.[173,174] In experienced hands the risk of procedure-related perinatal loss after IVT is 1.6% per procedure.[168] Some perinatologists routinely administer a muscle relaxant drug before IVT to prevent fetal movement, but others use it selectively or rarely. Transfusion volume should be optimized.[175,176] Complications include fetal bradycardia, cord hematomas, thrombosis or bleeding, rupture of membranes, infection, and premature labor.

Blood for Intrauterine Transfusion

No recent general guidelines have been published for many aspects of intrauterine transfusions. Although advances in equipment design and blood banking techniques have undoubtedly been made, reports of their application to intrauterine transfusion have not been published in peer-reviewed literature. By extrapolation from principles of neonatal transfusion therapy, it seems reasonable to propose that cytomegalovirus-negative packed RBCs should be used for intrauterine transfusion. Cells should be as fresh as is compatible with careful screening and crossmatch against maternal blood and should be leukocyte depleted and irradiated. The risk of graft-versus-host disease is very low but not zero.[177,178] The use of Kell antigen–negative blood is optimal, if it is available.

Treatment of the Neonate with Hemolytic Disease

General Measures

As a result of advances in antenatal assessment and treatment, the pediatrician often has the benefit of treating an infant with HDFN whose condition is better and whose disease course is more predictable than those of infants with HDFN in previous decades. The management of the infant with severe hydrops fetalis remains difficult, and because the disease is now uncommon in high-resource countries, there is reduced opportunity for well-designed trials to test various approaches to management. Uncertainties include the role of antenatal drainage of pleural effusions and ascites, which resuscitation fluids and drugs to use, and what criteria should be used for exchange transfusion. Hydropic fetuses often require extensive resuscitation at birth, including intubation (which can be complicated because of general edema), mechanical ventilation using high pressures, and prompt drainage of pleural effusions or ascites to facilitate lung expansion. Surfactant therapy may be necessary because of prematurity or surfactant inactivation.[179,180] Top-up

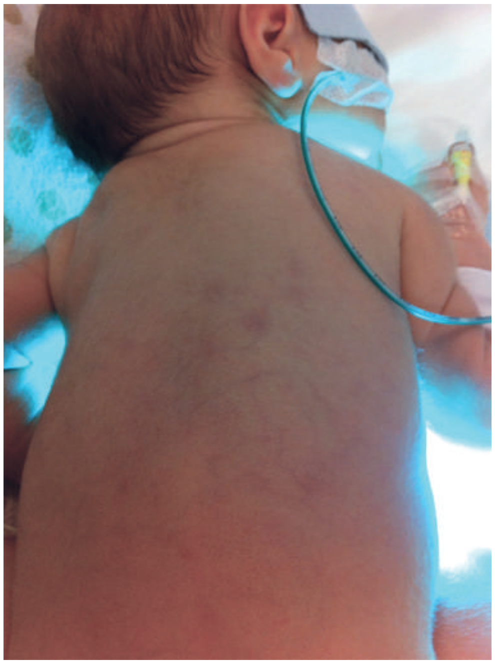

Figure 3-9 Photograph of palpable purpuric lesions that likely represent intradermal erythropoiesis on the back of an infant receiving phototherapy for severe RhD hemolytic disease.

transfusion may be useful for stabilization in hydropic infants who are severely anemic and may have low central venous pressures.[181]

Even in the mildly affected infant, careful assessment and anticipatory management are required. The fetus who has coped well in the intrauterine environment and has not needed or has responded well to intrauterine treatment can still have significant problems with the transition to independent extrauterine life. Problems attributable to HDFN such as hyperinsulinemic hypoglycemia[182,183] may be compounded by the problems of prematurity. The baby should be assessed promptly at birth and resuscitated if necessary. Physical examination may reveal hepatic and splenic enlargement and signs of anemia, including intradermal erythropoiesis (Fig. 3-9). Occasionally, stigmata resulting from accidents of intrauterine therapy are found.

Laboratory assessment should include a complete blood count, albumin level, assessment of blood group and relevant antibodies, and baseline measurement of (conjugated and unconjugated) bilirubin level so that the rate of increase of bilirubin can be calculated. In severely affected infants, liver function, acid-base balance, and coagulation profile should also be assessed. Cord blood can be useful for these tests but may provide misleading results unless the sample is promptly obtained and processed. Many blood banks will not accept cord blood for crossmatch. In infants who have received multiple transfusions, assessment of iron status should be considered,[184] especially if there is evidence of liver dysfunction.[185-188]

In regard to general care, breastfeeding should commence early in infants who are not deemed likely to need exchange transfusion. Infants who are mature and in good condition can be breastfed while receiving phototherapy by way of a suitable fiberoptic blanket or spotlight. Although Rh antibodies are present in breastmilk, particularly in colostrum, very little antibody is absorbed.[189] There is no evidence that forced fluid administration (beyond requirements for nutrition and compensation for any increased insensible losses) improves the outcome of the disease, and it is hazardous in premature infants and those in heart failure.

Folate is normally stored in the liver in late gestation, but reserves may be deficient in premature infants and depleted by ineffective erythropoiesis or by exchange transfusion, which replaces the infant's blood with adult blood that has a lower folate level. Supplemental folic acid at a dose of 50 to 200 μg/day is recommended to approximately 3 months of age.[190] Vitamin B_{12} is usually supplied in adequate amounts in breastmilk (unless the mother has a deficiency). Supplemental iron is not only unnecessary (because of increased iron storage at birth) but potentially hazardous.[184,186,190] Drugs that interfere with bilirubin binding to albumin or with bilirubin metabolism should be avoided.

Intensive phototherapy implies the use of high levels of irradiance distributed to as much of the infant's surface as possible. In intensive phototherapy the diaper should be removed to achieve optimal surface area exposure. Intensive phototherapy consists of at least two phototherapy lamps above and a fiberoptic pad under the infant. The use of phototherapy and other measures for hyperbilirubinemia is discussed in Chapter 4. The principles we now apply in deciding when to begin and end phototherapy in infants with HDFN have not, for the most part, been validated in well-designed trials. However, it seems likely that phototherapy is effective in preventing many exchange transfusions in infants with hemolysis.[191] Only limited evidence supports lower thresholds for using phototherapy and exchange transfusion for hemolytic than for nonhemolytic jaundice with respect to the risk of neurologic sequelae,[192] but it is common to use lower thresholds for phototherapy in HDFN to minimize the need for exchange transfusion. Most neonatal units experienced in care of infants with HDFN use intensive phototherapy prophylactically for infants at high risk and in others whenever there are high or rapidly rising bilirubin levels. The risks and resource implications of phototherapy are low compared with those of exchange transfusion.

Neonates with HDFN require, on average, 5 days of phototherapy, although there is a wide range.[193] It is standard practice to discontinue phototherapy lights one by one when serum bilirubin levels decrease and need for an exchange transfusion becomes less likely. It is also standard to reduce or discontinue phototherapy if the conjugated fraction of bilirubin increases substantially (e.g., to a third to half the total bilirubin level), although there is no good evidence as to what threshold should be used. Commonly, well near-term infants who have received intrauterine transfusions can be discharged by about 1 week of age.[180] Conversely, many weeks of tertiary-level neonatal intensive care may be needed for premature infants and very anemic prehydropic or hydropic infants.

The administration of IVIG to prevent the need for exchange transfusion in HDFN has been the subject of investigation.[194] These studies used different IVIG preparations and for different thresholds. Meta-analysis of all trials suggests a benefit, but the only two high-quality trials found no difference in need for exchange transfusion, peak serum bilirubin, or duration of phototherapy.[195,196] IVIG therapy may merit further investigation, but there is insufficient published evidence to recommend it outside of further carefully conducted clinical trials, and intensive phototherapy and preparation for exchange transfusion should not be delayed in the expectation that IVIG will be effective.

Exchange Transfusion

Exchange transfusion originated in the 1920s in a procedure done by way of the anterior fontanelle. Refinements to the technique of "exsanguination transfusion" were introduced by Wallerstein and Wiener in 1946.[197,198] Generations of infants and pediatric residents should be grateful that Diamond pioneered the use of umbilical catheters[199] because Wiener's technique involved infusion of blood through a saphenous vein cutdown and drainage (after heparinization of the baby) through an incision in the radial artery at the wrist. A randomized controlled trial in 1952 confirmed that the technique could save lives and prevent kernicterus.[200]

During exchange transfusion RBCs coated with antibody are replaced with RBCs negative for the antigen to which the mother is alloimmunized. Exchange transfusion corrects the anemia of the severely affected newborn, mitigates hyperbilirubinemia by removing the infant's hemolyzing erythrocytes and suppressing erythropoiesis, removes some of the already formed bilirubin, and depletes unbound anti-D antibody. Only modest amounts of the offending antibody are removed by exchange transfusion because unbound antibody is widely distributed in extracellular fluid, both within and outside the vascular compartment.

Indications for Exchange Transfusion. Exchange transfusion is generally performed when phototherapy and other conservative measures fail to control the bilirubin level, according to American Academy of Pediatrics (AAP) guidelines.[201] Although these guidelines provide thresholds for exchange transfusion that are lowest in the first hours after birth, neonatal intensive care units that have prompt blood bank support and the ability to perform exchange transfusion at short notice will often make preliminary preparations but delay commencing exchange transfusion in babies who do not have symptomatic anemia for at least several hours after birth in order to assess the effect of intensive phototherapy and to allow the procedure to be performed with optimal safety (e.g., in a neonatal intensive care unit, in daylight hours, with optimal staffing). The decision is complicated by imprecise knowledge regarding the risk boundaries for serious procedure-related morbidity on the one hand and bilirubin-induced brain injury on the other.

Free Bilirubin and Reserve Albumin Binding Studies. It appears that the level of free unconjugated bilirubin is the determining factor in the pathogenesis of bilirubin encephalopathy (kernicterus; see Chapter 4). Measurements of free bilirubin are not routinely available to guide clinical practice, but the AAP guidelines suggest taking the bilirubin-to-albumin ratio (which correlates with free bilirubin) into account in determining the threshold for phototherapy.[201]

Technique of Exchange Transfusion. Because the specific technical details of exchange transfusion are clearly described elsewhere,[202] they are discussed only briefly here. The safest location for catheter tips and whether it is better to use a single catheter "push-pull" technique or a double-catheter continuous technique have not been conclusively determined. In practice, these decisions are often based on local tradition and on the number and type of catheters that can be easily inserted. The procedure most often used in the authors' institutions consists of withdrawing blood in aliquots through an arterial catheter, with timing of each aliquot carefully matched to a continuous infusion (using a peristaltic pump) of donor blood into an umbilical or other venous catheter. Compared with techniques using both bolus withdrawals and injections, this method seems likely to reduce the risk of human error and avoids the need for rapid injection of boluses of donor blood. Regardless of technique, the procedure should be conducted precisely and with meticulous attention to precautions against infection. A second operator records the infusion and each withdrawal, plus the baby's vital signs and results of blood gases, blood sugar, and ionized calcium.

The blood should be ABO compatible and, for anti-D HDFN, Rh negative. If the mother is alloimmunized to an antigen other than D, the blood should be missing that antigen. It should be crossmatch compatible with the mother's serum. Ideally, the blood should also be negative for Kell antigen (to keep from sensitizing the infant) and hemoglobin S (to prevent problems with filtration). If the initial exchange transfusion is carried out using group O blood, any further exchange transfusions should use group O blood. Otherwise, brisk hemolysis and jaundice resulting from ABO incompatibility may become a further complication. Graft-versus-host disease occurs rarely after exchange transfusion, but blood should be irradiated if possible, especially for premature infants. The question of whether to use whole blood or packed RBCs partially reconstituted with plasma or saline (plus or minus platelets) has not been subjected to a rigorous study, but component therapy is increasingly widely used. Component therapy potentially exposes the infant to more donors and greater risk of handling errors, but less risk of white blood cell–related complications. For very unusual antibodies or combinations of antibodies, it may be necessary to transport RBCs over long distances. Occasionally, stored washed maternal RBCs must be used. In these circumstances, whole blood is unlikely to be available.

Depending on the local strategy for neonatal screening for metabolic and other diseases, it is strongly recommended that some of the blood from the first drawback be applied to a neonatal screening card. Otherwise, the diagnosis of some disorders, such as galactosemia, may be masked for some time to come. If any blood for serologic analysis or a DNA sample is needed for other diagnostic purposes, such as congenital infection, it should also be collected at this time.

Aliquots of the infant's blood are removed and replaced with antigen-negative donor blood. In choosing a technique for transfusion, the practitioner should take into account the following considerations: the infant's tolerance of the metabolic, hemodynamic, and hematologic demands; the effectiveness of the procedure in treating anemia and preventing an increase in bilirubin level; and safe handling of the blood for transfusion. The size of aliquot (generally 3 to 5 mL/kg) should be chosen to take into account the tolerance of the infant, and if a single catheter is used, its dead space. Principles of calculus make it clear that the largest aliquots the infant can tolerate will correct anemia most rapidly, but very rapid correction of anemia is not usually the prime objective. Allowing sufficient time for equilibration of bilirubin and antibody between vascular and extravascular compartments is another concern, but with very long procedures there is the risk of clotted catheters and degradation of the donor blood. Generally, between 1.5 and 2 infant blood volumes are exchanged (130 to 170 mL/kg of body weight) over about 2 to 3 hours.[202,203] A two–blood volume exchange transfusion removes approximately 90% of the affected RBCs of the infant, but the response is asymptotic rather than linear and 70% removal occurs after the first blood volume has been exchanged. Only about 25% to 30% of total bilirubin is removed because it is sequestered in extravascular and cellular compartments. A decrease of about 50% in the serum bilirubin level can be expected, but a rapid rebound to about 75% of the pre-exchange level typically is seen. The results of a recent randomized controlled trial suggest that two sequential single-volume exchange transfusions (with about a 3-hour interval between transfusions) may reduce the rate of rebound serum bilirubin level and decrease the need for repeated exchange transfusions, when compared with a single-stage, double volume exchange transfusion.[204]

Many earlier guidelines suggested routine administration of calcium gluconate. However, contemporary anticoagulants affect the ionized calcium much less than the citrate-phosphate-dextrose used in previous years. Furthermore, most neonatal units now have immediate access to blood gas analyzers that also measure ionized calcium, electrolytes, and glucose in small samples. Periodic measurement of ionized calcium, electrolytes, glucose, and blood gas is therefore a good alternative (e.g., every 30 minutes or earlier if the infant manifests any instability). Continuous electrocardiographic monitoring and oximetry should be performed.

Complications of Exchange Transfusion. Complications of exchange transfusion include all those of simple transfusion plus a variety of others related to the large size of the transfusion, to the catheters, and to the technique.[205,206,180]

Mortality rates have been estimated at 0.5% to 2%, but most studies are too small to estimate the risk precisely. Furthermore, the risk for each infant may be influenced by many factors, particularly prematurity and prior severity of illness.

Exchange transfusion produces a significant drop in leukocyte levels, and this is associated with increased risk for culture-proven sepsis, necessitating a high index of suspicion.[180] However, leukopenia and subsequent "left shift" during the rebound from it can also complicate the diagnosis of sepsis in the hours and days after exchange. A similar decrease in platelets is reported after exchange transfusion, with an associated increased risk of hemorrhage. Because of the risk for intraventricular hemorrhage,[180,207] platelet therapy should be considered in sick and premature infants who manifest thrombocytopenia. Platelet count should be measured before, half-way through, and after an exchange transfusion to detect and treat severe thrombocytopenia. Hypocalcemia is also common (because of the use of citrate in donor blood) and could contribute to the risk of hemorrhage in the presence of other coagulation defects.

Necrotizing enterocolitis is a potentially life-threatening hazard that may be related to the technique. In the absence of evidence-based guidelines, effort should be made to prevent wide pressure and volume variations during exchange transfusion. Blood injection and withdrawal should be carried out smoothly without undue haste. Prolonging the interval until oral feeding is restarted and administering prophylactic antibiotics or probiotics might also influence the risk of necrotizing enterocolitis, but there is currently no clear evidence for any of these practices in relation to exchange transfusion.

Declining experience with exchange transfusion among neonatal and pediatric medical and nursing staff as fewer procedures are performed may be counterbalanced by the use of detailed, standardized protocols and improvements in other aspects of intensive care. However, the performance of exchange transfusions in neonatal intensive care units with experienced staff and with blood banks familiar with supplying neonates is likely to yield the best results for infants and the best hope of accumulating evidence to guide future practice.

MANAGEMENT OF SPECIAL PROBLEMS

Syndrome of Hepatocellular Damage

Obstructive jaundice is frequent in infants with HDFN, occuring in 13% in one study, of whom a quarter had conjugated bilirubin levels exceeding half the total bilirubin level.[188] RhD HDFN and intrauterine treatment increased the risk. In a few infants there is extreme hepatomegaly and other clinical evidence of biliary canalicular obstruction. Some infants may develop extreme or prolonged cholestasis, necessitating fat soluble vitamin supplements or other management. The need for chelation for iron overload has also been reported.[187,188]

Infants Who Have Undergone Fetal Transfusions

Assessment of infants who have undergone IVT or IPT does not differ from that of other babies with HDFN.

After multiple IVTs these infants may be delivered with few residual Rh-positive hemolyzing RBCs; their early neonatal management may be simple. However, a high proportion still require one or more exchange transfusions and later top-up transfusions.[208] Multiple transfusions often suppress erythropoiesis (reduced reticulocyte count at birth), leading to an increased need for top-up transfusions to treat neonatal anemia. In addition, thrombocytopenia is often detected in HDFN and is increased in infants treated with intrauterine transfusions.[209]

Follow-Up Care of the Infant with Hemolytic Disease

Whether or not the affected infant has required fetal transfusions or exchange transfusions, anemia in the first few weeks of life is common.[190] Hemoglobin levels should be checked at 7- to 14-day intervals until the hemoglobin has stabilized (usually at approximately 8 to 12 weeks of age). The anemia is due to the gradual loss of transfused Rh-negative RBCs and to the failure of the infant's Rh-positive RBCs to replace them. This failure is initially caused by hemolysis of any RBCs produced and by transient erythroblastopenia, which usually resolves spontaneously at about 6 to 8 weeks of age. The risk is increased by prior intrauterine treatment and decreased by exchange transfusion.[190,208,210]

On average, neonates with HDFN require one top-up transfusion within the first 3 months after delivery.[190] In rare cases, however, some neonates may require up to six top-up transfusions. If symptomatic anemia develops or if hemoglobin levels are falling rapidly toward symptomatic levels, a simple transfusion of 15 to 20 mL/kg of body weight of crossmatched, packed RBCs compatible with the infant's serum is administered. In the authors' institutions, usual hemoglobin thresholds for top-up transfusion are approximately 7.2 to 8 g/dL for asymptomatic babies and approximately 9.6 g/dL for symptomatic babies. Use of these restrictive thresholds for asymptomatic babies after discharge from hospital depends on very good follow-up and rapid access to transfusion if symptoms develop. It is important to remember that international consensus regarding the optimal hemoglobin level threshold for transfusion is lacking.

Recombinant erythropoietin has been used with some success in the treatment of the anemia of prematurity. Its use for prevention of "late" anemia in infants with HDFN has been tested in small trials.[211-213] A larger trial is needed to evaluate the role of erythropoietic stimulating agents in mitigating late anemia of HDFN.

Long-Term Neurodevelopment Outcome After Severe Fetal Anemia

In a recent long-term follow-up study on the neurodevelopment outcome after severe fetal anemia in HDFN treated with intrauterine transfusions (LOTUS study), the risk of neurodevelopmental impairment was reported to be low (4.8%). Severe fetal hydrops was independently associated with neurodevelopmental impairment (odds ratio 11.2; 95% confidence interval, 1.7-92.7), suggesting that prevention of fetal hydrops by timely detection, referral, and treatment may improve long-term outcome.[171]

OTHER MATERNAL ALLOANTIBODIES CAUSING FETAL AND NEONATAL HEMOLYTIC DISEASE

Alloantibodies Other than A and B

Although reports from numerous geographic areas demonstrate the effectiveness of administration of anti-D IgG to prevent RhD alloimmunization, most find that Rh is still the blood group system causing most cases of HDFN and anti-D is still the most common single antibody causing severe HDFN. Of non-D Rh antigens, anti-c is the next most important cause of clinically significant HDFN (although it is typically surpassed in severity, and in many countries in frequency, by anti-Kell HDFN—discussed later). About half of anti-c antibodies are caused by transfusion, and they are often present at low titer or the fetus is c-negative. However, anti-c can cause severe HDFN or fetal death, and careful assessement is warranted.[214] Anti-E is relatively common but most commonly causes only mild HDFN.[215] A wide variety of other non-D Rh antigens, such as anti-C, anti C^w, and anti-e, have also been reported to very occasionally cause moderate or severe HDFN.[216,217] Rh antigens are not infrequently found in combination, such as anti-D plus –C, –D plus –E, or –c plus –ce. Often, one of the antibodies (e.g., anti-D) is present in higher titer and has the predominant influence on disease severity, but the combination adds to the complexity of finding suitable donors for intrauterine, exchange, or top-up transfusion.

There are at least 26 blood group systems, with more than 900 alleles of 39 genes, and the molecules carrying these antigens are very diverse in structure, function, and tendency to cause HDFN. The molecules include transporters and channels (e.g., Diego, Kidd, Colton, and Rh), receptors for pathogens (Duffy, P, and others) and for adhesion to other cells (e.g., Landsteiner-Wiener), enzymes (ABO, H, Lewis, P, and Kell), structural proteins (Ge), and complement receptors (Ch/Rg)[16,218] (see Chapters 15 and 36).

As the incidence of RhD HDFN has been decreasing, other blood group antibodies have assumed a greater importance. Through the interval when anti-D immunoprophylaxis became available, Bowman[219] found that in Manitoba, Canada (population 1 million), the mean annual occurrence of D alloimmunization in pregnant women dropped from 194 in 1962 through 1967 to 23 in 1989 through 1994. In the same two periods, the mean annual occurrence of detected non-D alloimmunization in pregnant women, excluding ABO alloimmunization, increased from 14 to 108. This increase was partially the result of the increased screening of pregnant D-positive women. It also reflected a real increase in the occurrence of non-D alloimmunization because of the increased incidence of blood transfusion (transfused blood is generally only crossmatched for ABO and D). A summary of results from eight studies from the 1960s to the 2000s is shown in Table 3-6.

There is marked international variation in frequency and distribution of alloantibodies. For example, in Asian countries where RhD negativity is rare, so is anti-D. Lee and colleagues identified one case in 28,303 women in

Hong Kong over a 5-year period, and Rh antibodies accounted for only 27.3% overall. Anti-Mi, recognizing an antigen in the MNS blood group system, was about twice as common, and although it caused no cases of severe HDFN in this series, its potential to do so has been reported.[220]

The alloantibodies listed by various authors as having been reported to cause HDFN are listed in Table 3-7.[42,216,221] Of the multitude of antibodies implicated as causes of HDFN, fortunately most are rare or rarely cause severe disease (Table 3-8). Some are the subject of single case reports.

There are various reasons that the incidence and severity of HDFN differ from one blood group antigen system to another. In some cases it is because of the rarity of the offending antigen or the lack of it and the likelihood of incompatibility between parents being low. An example is the Colton blood group system, which comprises the high-incidence antigens Co$_{a}$ and Co$_{3}$ found on aquaporin-1. Rare individuals lacking this aquaporin can produce antibodies that lead to severe HDFN.

TABLE 3-7 Non-ABO Alloantibodies Reported to Cause Hemolytic Disease[42,219,221]

	Any HDFN	Can Cause Moderate or Severe HDFN
Within the Rh system	Anti-D, -c, -C, -C^{w}, -C^{x}, -e, -E, -E^{w}, -ce, -ceBI -Ce^{s}, -Rh32, -Go^{a}, -Be^{a}, -Evans, -Rh17	Anti-D (commonly) Anti-c, -C, -C^{w}, -C^{x}, -e, -E, -E^{w}, -ce, -Ce^{s}, -Rh32, -Go^{a}, -Be^{a}, -Evans, -Rh17
Outside the Rh system		
Kell	Anti-K, -k, -Ku, -Kp^{a}, -Kp^{b} , -Jk^{a}, -Jk^{b} -Js^{a}, -Js^{b},	Anti-K (commonly) Anti-k, -Kp^{a} -Jk^{a}, -Js^{a}, -Js^{b}, -Ku
Duffy	Anti-Fy^{a}, -By3	Anti-Fy^{a}
Kidd	Anti-Jk^{a}, -Jk^{b}, -Jk^{3}	Anti-Jk^{a}
MNSs	Anti-M, -N, -S, -s, -U, -Mi^{a}, -M^{v}, -Mit	Anti-M, -S, -s, -U, -Mi^{a}
MSSs	Anti-Mt^{a}, -Mur, -Hil, -Hut	Anti-Mt^{a}

Xg	Anti-Xg^{a}	Anti-LW
P	Anti-PP$_{1pk}$	Anti-PP$_{1pk}$
Examples of antibodies to other low-frequency antigens	Anti -By, -Fr^{a}, -Sc2, -Rd, -Re^{a}, -Zd, -Vw, -Batty, -Becker, -Berrens, -Biles, -Gonzales, -Good, -Heibel, -Hunt, -Jobbins, -Radin, -Rm, -Ven, -Wr^{a}, -Wr^{b}, -Zd	Anti-Biles, -Good, -Heibel, -Wr^{a} -Zd
Examples of antibodies to high-incidence antigens	Anti-At^{a}, -Co^{a}, -En^{a}, -Do^{a}, -Ge, -Jr^{a}, -Lan, -Yt^{a}, -Yt^{b}	Anti-Co^{a}, -En^{a}, -Lan, -Yt^{a}

HDFN, Hemolytic disease of the fetus and newborn.

*Anti-Lewis, anti-I and -Fy^{b} antibodies do not cause HDFN of any severity. For antibodies that can cause moderate or severe HDFN, assessment of risk, including paternal typing and fetal surveillance, should be considered if the antibodies are present at or above the critical titer for the laboratory or are rising. Note that Kell antibodies can cause severe HDFN at relatively low titers. More than one antibody can coexist, and prognosis may depend most on the antibody with the highest predilection for causing HDFN, even if it is not present at the highest titer.

In others it is because of low levels of expression on the RBC surface. For this reason maternal anti-I and anti-Lutheran antibodies, even when present at high titer, usually do not cause HDFN because of low cell surface expression of these antigens on fetal RBCs. Lutheran antigens are also widely distributed in endothelial cells.

Disease caused by anti-Kell antibodies can be very severe. Maternal antibodies to KEL1 causing neonatal anemia were first described in 1945,[5] and the blood group system was named for the woman in whom the antibodies were found. Kell glycoprotein is an endopeptidase involved in endothelin activation,[218,221] and it is more properly regarded as a subunit of a larger protein because it is linked by disulfide bond to the XK protein. Absence of XK can cause weak Kell expression and dysfunction of other organs (McLeod syndrome). Null Kell alleles also occur. Redman and associates[222] reviewed the Kell blood group and summarized the low- and high-incidence antigens, of which approximately 25 have been described. They occur as variants of several epitopes. The most immunogenic antigen, KEL1, is second to RhD in its immunizing potential and occurs in about 9% of white subjects and 2% percent of black subjects. It results from a point mutation causing a Thr193 (KEL2) to Met193 (KEL1) substitution, which in turn leads to loss of a glycosylation site. The other Kell phenotypes are also generally caused by single base substitutions, so genotyping is more straightforward than that in the Rh system.

Sensitization occurs most commonly through unmatched blood transfusion but can arise during pregnancy. Although the number of incompatible pregnancies is lower for Kell than for RhD, the proportion of anti-KEL1–affected fetuses that are severely affected is thought to be 20% or higher.[223-227]

Kell antibodies, which recognize antigens expressed in early erythroid progenitors and at an early stage of erythropoiesis in fetal liver, appear to be capable of suppressing erythropoiesis.[228] This is the putative reason for the tendency for hydrops early in pregnancy seen in anti-Kell HDFN. It has also been proposed as the reason that amniotic fluid spectrophotometry is not as reliable as in Rh hemolytic disease, although not all studies agree on this point.[224,229,230] Paternal typing followed, where necessary, by fetal genotyping and early, close monitoring by ultrasound is recommended in pregnancies complicated by anti-Kell antibodies. Because of the suppression of fetal erythropoiesis, the immediate neonatal management in Kell HDFN is different from RhD HDFN. As shown in a recent study, neonates with Kell hemolytic disease require less phototherapy and fewer exchange transfusions compared with neonates with RhD hemolytic disease, but an equal number of top-up transfusions.[227]

There are rare instances of a wide variety of other alloantibodies, usually benign ones, causing hemolytic

disease sufficiently severe to require intrauterine or postnatal treatment (e.g., anti-Coa, anti-Fya, anti-Di, and anti-M).

ABO Hemolytic Disease

ABO HDFN behaves differently from HDFN because of either anti-D or other blood group antibodies. Anti-A and anti-B, which bind complement in adults, cause violent, life-threatening intravascular hemolysis after transfusion of ABO-incompatible blood. However, although kernicterus may develop if the baby with ABO HDFN is left untreated, symptomatic fetal, neonatal, or late anemia is very rare. There are occasional reports of hydrops fetalis attributed to ABO erythroblastosis.[231] It is possible that some of these involve other causes of increased ineffective erythropoiesis (such as RBC enzyme deficiency or α-thalassemia trait) or nonimmune hydrops superimposed on ABO HDFN. If clinically significant anemia or hydrops is found in a fetus or newborn with a positive direct antiglobulin test (DAT) owing to anti-A or anti-B, other potential etiologies should still be investigated. Some but not all series have found that ABO antibodies are a more common cause of HDFN (and of severe HDFN) in Southeast Asia, Africa, and Latin America, for reasons that have yet to be determined.[42]

Several reasons have been proposed for the mildness of ABO HDFN compared with HDFN caused by other antibodies and with adult ABO hemolysis.[232] First, there are fewer A and B antigenic sites on the fetal RBC membrane,[233] and anti-A and anti-B do not bind complement on the fetal RBC membrane.[234] Second, anti-A and anti-B are often IgM, which does not cross the placenta, or IgG2, which plays a minor role in HDFN.[235] Third, the small amounts of IgG anti-A and anti-B that do traverse the placenta have myriad antigenic sites both on tissues other than on RBCs and on secretions to which they may bind. Because there is very little antibody on the RBC, the cord blood direct antiglobulin test result in ABO hemolytic disease is usually only weakly positive and may be negative unless a sensitive test is used. Capillary blood taken at 2 or 3 days of age often yields a negative direct antiglobulin test result regardless of test sensitivity. In at least 25% of ABO-incompatible babies, cord blood RBCs give weakly positive results on the direct antiglobulin test at delivery, and an excess of babies with blood types A and B of mothers with blood type O become severely jaundiced.[236,237] The A- or B-incompatible infants of mothers with blood type A or B do not appear to be at increased risk for hemolysis or jaundice.[238]

However, only a small fraction of A- or B-incompatible infants of O mothers develop clinical evidence of HDFN (early and severe jaundice), even when the direct antiglobulin titer is positive.[238-240] One study found that only 0.07% of more than 88,000 infants required exchange transfusion for anti-A or -B HDFN.[239] Nevertheless, ABO HDFN continues to account for a significant proportion of infants with troublesome jaundice, necessitating prolongation of hospital stay, readmission to the hospital, or home therapy. The same large study found that ABO incompatibility accounted for 5.5% of infants with jaundice.

Although anemia is rarely severe, mild hemolysis appears to be common. In a series of 1704 infants of blood group O mothers, the infants with blood group A or B had significantly higher cord bilirubin and lower cord hemoglobin concentrations than the babies with blood group O.[241] Blood films may show polychromasia, reticulocytosis, and prominent spherocytosis, which can sometimes be difficult to differentiate from hereditary spherocytosis.

Control of hyperbilirubinemia is usually the major issue in infants with ABO HDFN, and thresholds for phototherapy and exchange transfusion are generally regarded as similar to those for Rh HDFN. The risk of symptomatic late anemia in ABO HDFN is very low. The risk of recurrence of jaundice caused by anti-A or -B in future incompatible siblings is high, and mothers should be counseled accordingly.[242]

CONCLUSIONS

Advances in prevention of Rh sensitization and the management of immune HDFN in the past 30 years have been dramatic. Statistics from high-resource countries have indicated that the prevalence of Rh sensitization in pregnant women has been reduced by more than 90%, although worldwide the disease burden remains large.[89] The number of exchange transfusions has also decreased by more than a hundredfold. In addition, the number of perinatal deaths caused by HDFN has plummeted. However, for those still affected by anti-D or other significant antibodies, the disease burden remains significant.

Despite a recent explosion in knowledge about antigen presentation and provocation of the immune response in general, little detail at the molecular and cellular level is known about maternal sensitization to RhD. A better understanding of these events, taken together with the recent elucidation of the molecular genetics of RhD and other blood groups, is likely to provide new tools for prevention, diagnosis, and treatment.

    Systematic review of the evidence for RhD immunoglobulin during pregnancy for prevention of RhD sensitization.
81. Liumbruno GM, D'Alessandro A, Rea F, et al: The role of antenatal immunoprophylaxis in the prevention of maternal-foetal anti-Rh(D) alloimmunisation. *Blood Transfus* 8:8–16, 2010.
    A useful comparison of international guidelines for immunoprophylaxis using RhD immunoglobulin.
83. Karanth L, Jaafar SH, Kanagasabai S, et al: Anti-D administration after spontaneous miscarriage for preventing Rhesus alloimmunisation. *Cochrane Database Syst Rev* (3):CD009617, 2013.
    Systematic review that summarizes the relatively sparse evidence for RhD immunoglobulin after spontaneous miscarriage.
84. Maayan-Metzger A, Schwartz T, Sulkes J, et al: Maternal anti-D prophylaxis during pregnancy does not cause neonatal haemolysis. *Arch Dis Child Fetal Neonatal Ed* 84:F60–F62, 2001.
    The authors assessed 101 babies who had been exposed to zero, one, or two doses of antenatal RhD immunoglobulin and found no differences in hemoglobin, hematocrit, reticulocyte count, or hyperbilirubinemia, although a few infants had a positive DAT (mostly after exposure to two maternal antenatal doses). This paper is important in estabilishing the safety for the infant of maternal RhD immunoprophylaxis in pregnancy.
86. Kim YA, Makar RS: Detection of fetomaternal hemorrhage. *Am J Hematol* 87:417–423, 2012.
    Detailed recent review of the characteristics of currently available qualitative and quantitative assays for fetal cells in maternal blood, with an emphasis on detection of fetomaternal hemorrhage in RhD-positive fetuses of RhD-negative mothers to guide administration of RhD immunoglobulin.
87. Adams MM, Marks JS, Gustafson J, et al: Rh hemolytic disease of the newborn: using incidence observations to evaluate the use of RH immune globulin. *Am J Public Health* 71:1031–1035, 1981.
89. Zipursky A, Paul VK: The global burden of Rh disease. *Arch Dis Child Fetal Neonatal Ed* 96:F84–F85, 2011.
    Although RhD HDFN is a particular risk in European populations where RhD-negative blood type is most common (approximately 15%), RhD negativity also occurs in African and Asian countries (e.g., India and Nigeria, 5%; and Pakistan, 7.5%) where RhD immunoprophylaxis is not universally available. The authors' estimate of the global burden of HDFN explains that this disease, which represents one of the early success stories of obstetrics in North America and Europe, remains a serious cause of mortality and morbidity elsewhere.
125. Geifman-Holtzman O, Grotegut CA, Gaughan JP: Diagnostic accuracy of noninvasive fetal Rh genotyping from maternal blood—a meta-analysis. *Am J Obstet Gynecol* 195:1163–1173, 2006.
    Systematically reviews and presents the accuracy of published series to 2005 and comments on the utility, standards for benchmarking, and potential pitfalls of this form of fetal assessment.
139. Pretlove SJ, Fox CE, Khan KS, et al: Noninvasive methods of detecting fetal anaemia: a systematic review and meta-analysis. *BJOG* 116:1558–1567, 2009.
    This evaluation of the accuracy of studies using ultrasound methods for assessing the severity of fetal anemia to determine management asserts that MCA-PSV is the best validated and likely the most accurate and is comparable with results from amniotic fluid spectroscopy. Nevertheless, the accuracy (across 25 studies enrolling 2163 women) is relatively low and varies between studies, highlighting the importance of ongoing quality assurance and awareness of the limitations of the test.
141. Moise KJ, Jr, Argoti PS: Management and prevention of red cell alloimmunization in pregnancy: a systematic review. *Obstet Gynecol* 120:1132–1139, 2012.
    The authors evaluated reports from 1990 to 2012 addressing various aspects of prevention of alloimmunization in pregnancy and its subsequent management, selecting 246 for inclusion in the review. The paper includes useful diagrammatic algorithms for determining fetal RHD type and clinical management in the red cell alloimmunized pregnancy.
155. ACOG Practice Bulletin No. 75: Management of alloimmunization during pregnancy. *Obstet Gynecol* 108:457–464, 2006.
    The most recent American College of Obstetricians and Gynecologists guidelines for management of pregnancy when there are antibodies to RhD or other blood group antigens detected during pregnancy, including a useful table of antibodies suggesting whether routine care or fetal assessment is indicated.
158. Liley AW: Intrauterine transfusion of foetus in haemolytic disease. *Br Med J* 2:1107–1109, 1963.

This report was momentous in establishing the specialty of maternal-fetal medicine, and it led the way for later improvements in fetal treatment. Subsequently, RhD immunoprophylaxis has done much more to prevent mortality and major morbidity, but fetal treatment remains critical for many fetuses, including those with non-RhD hemolytic disease of the fetus and newborn.

171. Lindenburg IT, Smits-Wintjens VE, van Klink JM, et al: Long-term neurodevelopmental outcome after intrauterine transfusion for hemolytic disease of the fetus/newborn: the LOTUS study. *Am J Obstet Gynecol* 206(141):e1–e8, 2012.

This study followed 291 survivors of severe HDFN requiring intrauterine transfusion to a median age of 8.2 years. The rate of neurodevelopmental impairment was low (4.8%). Hydrops increased the risk, suggesting that preventing hydrops in pregnancies at the highest risk may further improve outcomes.

180. Smits-Wintjens VEHJ, Rath MEA, van Zwet EW, et al: Neonatal morbidity after exchange transfusion for red cell alloimmune hemolytic disease. *Neonatology* 103:141–147, 2013.

This 10-year retrospective assessment of neonatal morbidity in infants with HDFN showed that infants who required exchange transfusion were at higher risk for sepsis, leukopenia, severe thrombocytopenia, hypocalcemia, and hyponatremia. No deaths occurred in the 134 who had exchange transfusion.

196. Smits-Wintjens VE, Walther FJ, Rath ME, et al: Intravenous immunoglobulin in neonates with rhesus hemolytic disease: a randomized controlled trial. *Pediatrics* 127:680–686, 2011.

This high-quality randomized, placebo-controlled blinded clinical trial, like that of Santos et al. (2013), showed no benefit of intravenous immunoglobulin in preventing exchange transfusion in infants with Rh HDFN, in contrast to previous unblinded studies.

210. Rath ME, Smits-Wintjens VE, Lindenburg I, et al: Top-up transfusions in neonates with Rh hemolytic disease in relation to exchange transfusions. *Vox Sang* 99:65–70, 2010.

In a retrospective review the authors show that using exchange transfusion criteria according to American Academy of Pediatrics 2004 guidelines reduced the proportion of babies with RhD, C, c, or E hemolytic who needed exchange transfusion, but somewhat increased the proportion who needed top-up transfusion for late anemia (and the number of top-up transfusions per baby).

227. Rath ME, Smits-Wintjens VE, Lindenburg IT, et al: Exchange transfusions and top-up transfusions in neonates with Kell hemolytic disease compared with Rh D hemolytic disease. *Vox Sang* 100:312–316, 2011.

This study in a center that manages a high volume of hemolytic disease of the fetus and newborn found that fetuses with Kell hemolytic disease needed intrauterine treatment at rates comparable to those with Rh HDFN. As neonates, they needed less phototherapy and fewer exchange transfusions than those with Rh HDFN, but they were nearly as likely to need top-up transfusion, indicating that like those with Rh HDFN, they are at high risk for late anemia.

238. Ozolek JA, Watchko JF, Mimouni F: Prevalence and lack of clinical significance of blood group incompatibility in mothers with blood type A or B. *J Pediatr* 125:87–91, 1994.

This study reports the prevalence and clinical significance of blood group incompatibility in 4996 consecutive liveborn infants whose mothers had blood type A or B. Of ABO incompatible mother-infant pairs, 13% of infants had a positive DAT (32%) if the mother was type O, but this was very unlikely if the mother was type A or B. Infants with a positive DAT had subtly lower cord hematocrit levels, but only one in five developed clinically significant jaundice.

INTRODUCTION

Elevation of the serum bilirubin level is a common, if not universal, finding during the first week of life and has been reviewed elsewhere.[1-4] This can be a transient phenomenon that will resolve spontaneously or can signify a serious or even potentially life-threatening condition. There are many causes of hyperbilirubinemia and related therapeutic and prognostic implications. Independent of the cause, elevated serum bilirubin levels can be potentially toxic to the newborn infant. This chapter will review perinatal bilirubin metabolism and address assessment, etiology, toxicity, and therapy for neonatal jaundice. The diseases in which there is a primary disorder in the metabolism of bilirubin will be reviewed regarding their clinical presentation, pathophysiology, diagnosis, and treatment.

BILIRUBIN METABOLISM

Bilirubin Production and Transport

In 1864 Städeler used the term *bilirubin,* derived from Latin (*bilis,* bile; *ruber,* red), for the red-colored bile pigment.[5] Bilirubin is formed from the degradation of heme-containing compounds (Fig. 4-1), the largest source of which is hemoglobin, and other sources are the cytochromes, catalases, tryptophan pyrrolase, and muscle myoglobin.[6]

The formation of bilirubin is initiated by cleaving the tetrapyrrole ring of protoheme (protoporphyrin IX), which results in a linear tetrapyrrole (biliverdin). The first enzyme system and rate limiting step in bilirubin synthesis is microsomal heme oxygenase (HO).[7] Two major forms of HO have been identified. HO1, the inducible form, is located in the spleen, liver, and bone marrow. HO2, the constitutive form, is located in testes, central nervous system (CNS), vasculature, liver, kidney, and gut.

HO results in reduction of the porphyrin iron (Fe^{III} to Fe^{II}) and hydroxylation of the α methine (=C-) carbon.

Bilirubin is frequently represented by any of the three structures (3-5) shown at the bottom. *(From Gourley GR: Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF, editors:* Liver disease in children, *ed 3, New York, 2007, Cambridge University Press.)*

This α carbon is then oxidatively excised from the tetrapyrrole ring, yielding carbon monoxide (CO); this is the only physiologic source of CO. This excision opens the ring structure and is associated with oxygenation of the two carbons adjacent to the site of cleavage. The cleaved α carbon is excreted as CO, which has numerous biological effects, including neurotransmission, vasodilation as well as mediation of apoptosis and anti-inflammatory processes.[7] The iron released by HO can be reutilized by the body. HO produces a linear tetrapyrrole, biliverdin IXα. The IX designation is a result of Fischer's grouping of the protoporphyrin isomers, group IX being the physiological source of bilirubin.[8] In utero, bilirubin IXβ is the first bile pigment seen and can be found in bile or meconium by 15 weeks' gestation.[9] Small amounts of bilirubin IXβ are also found in adult human bile.[10] The central (C-10) carbon on biliverdin IXα is then reduced from a methine to a methylene group (-CH_2-), thus forming bilirubin IXα. This is accomplished by the cytosolic enzyme biliverdin reductase.[11] The proximity of this enzyme results in very little biliverdin ever being present in the circulation.

Bilirubin formation can be assessed by measurement of CO production.[12] Such assessments indicate that the daily production rate of bilirubin is 6 to 8 mg/kg/24 hr in healthy term infants and 3 to 4 mg/kg/24 hr in healthy adults.[13,14] In mammals, 80% to 85% of bilirubin produced daily originates from hemoglobin.[15] Degradation of hepatic and renal heme appears to account for most of the remainder, reflecting the very rapid turnover of certain of these heme proteins. Although the precise fate of myoglobin heme is unknown, its turnover appears to be so slow as to be relatively insignificant.[16]

Catabolism of hemoglobin occurs very largely from the sequestration of erythrocytes at the end of their life span (120 days is adult humans, 90 days in newborns). A small fraction of newly synthesized hemoglobin is degraded in the bone marrow. This process, termed *ineffective erythropoiesis,* normally represents less than 3% of daily bilirubin production but may be substantially increased in people with hemoglobinopathies, vitamin deficiencies, and heavy metal intoxication.[17-19] Infants produce more bilirubin per unit of body weight because of their greater red blood cell mass and shorter red blood cell life span. Additionally, hepatic heme proteins represent a larger fraction of total body weight in infants.

Although bilirubin has long been thought of solely as a waste product, data suggest that some mild degree of hyperbilirubinemia may be helpful because of the antioxidant capacity of bilirubin and its potential role as a free-radical scavenger and cytoprotectant.[20]

Bilirubin is poorly soluble in aqueous solvents and thus requires biotransformation to more water-soluble derivatives for excretion from the body. This poor solubility is related to the structure of bilirubin.[21] Rather than being linear (structure 5, Fig. 4-1), bilirubin undergoes extensive internal hydrogen bonding (structure 4, Fig. 4-1). This shields the polar propionic acid side chains and makes bilirubin very nonpolar and lipophilic. The carbon–carbon double bonds at positions 4-5 and 15-16 can assume two different configurations (similar to *cis* and *trans*) depending on whether the higher priority atoms or groups (based on atomic number) are on the same (*Z, zusammen,* German: *together*) or opposite (*E, entgegen, opposite*) sides of the double bond. The naturally occurring form of bilirubin, 4Z,15Z-bilirubin IXα, can be represented by any of the three structures (3-5) depicted at the bottom of Figure 4-1. Knowledge of this stereochemistry is important in understanding phototherapy, which will be discussed later.

Bilirubin's poor aqueous solubility necessitates a carrier molecule, albumin, for transport from sites of production in the reticuloendothelial system to the liver for excretion (Fig. 4-2).[22] Each albumin molecule possesses a single high-affinity ($K_a = 7 \times 10^7\ M^{-1}$) binding site for one molecule of bilirubin.[23] A binding affinity of this magnitude implies that, at normal serum bilirubin levels, all bilirubin will be transported to the liver bound to albumin, with negligible amounts free to diffuse into other tissues. Secondary binding sites of lesser affinity also exist on albumin. Albumin also serves as a carrier for other compounds such as xenobiotics and fatty acids.

Hepatic Uptake of Bilirubin

The structure of the liver is well suited for the uptake of bilirubin by individual hepatocytes. Cords of hepatocytes are arranged radially so that adjacent sinusoids border all hepatocytes. The flow of blood through the sinusoids is slower than that of other capillary beds because it is generated by portal venous pressure rather than arterial pressure. There is easy passage of albumin-bound bilirubin from the plasma into the tissue fluid space (space of Disse) between the endothelium and the hepatocyte because the sinusoidal endothelium of the liver lacks the basal laminae, which are found in other organ capillary systems.[24] The pores of the endothelium allow direct contact with the plasma membrane of the hepatocyte.

A hepatocyte with a schematic illustration of bilirubin metabolism is shown in Figure 4-2. In the first step, bilirubin dissociates from its albumin carrier[25] and enters the hepatocyte via a membrane-receptor carrier, which facilitates entry into the hepatocyte. Carrier-mediated transport into the hepatocyte has been demonstrated for several organic anions including bilirubin, bromsulfophthalein (BSP), and indocyanine green (ICG),[26] though bilirubin has also been shown to be able to pass through membranes by simple passive diffusion.[27] Evidence suggests that bilirubin, BSP, and ICG share the same hepatocyte-receptor carrier because they exhibit competitive inhibition when injected simultaneously. This finding cannot be explained by subsequent intrahepatic metabolism, because these anions are handled differently by the hepatocyte: Bilirubin is conjugated with glucuronic acid in the endoplasmic reticulum (ER), BSP is conjugated with glutathione in the cytosol, and ICG is excreted directly without biotransformation. Data from rat hepatocytes suggest that the anion binding–receptor carrier is a dimeric protein with subunit molecular weight of 55,000.[28-30] Antibody studies confirm the expected location in the plasma membrane[29] and demonstrate blocking of uptake.[30] Organic anion transporting polypeptide 2 (OATP2, recently named OATP1B1 under

new nomenclature[31]) has shown high-affinity uptake of bilirubin in the presence of albumin and is a member of the OATP family, transporter symbol SLC21A.

Carrier-mediated transport of bilirubin into the hepatocyte is necessary because of differences in protein-binding inside and outside the hepatocyte. Outside the hepatocyte, bilirubin is bound to albumin (affinity constant ~10^8, concentration: 0.6 mM).[23] Inside the hepatocyte, bilirubin is bound to glutathione S-transferase B (GST), historically known as ligandin or the Y protein (affinity constant ~10^6, concentration 0.04 mM).[32,33] GST constitutes a family of proteins that exhibit important functions both as enzymes and as intracellular binding proteins for nonsubstrate ligands such as bilirubin.[34] Carrier-mediated uptake helps generate a concentration gradient for bilirubin uptake despite the difference in affinity between albumin and GST. GST is important in the intracellular storage of bilirubin and bilirubin

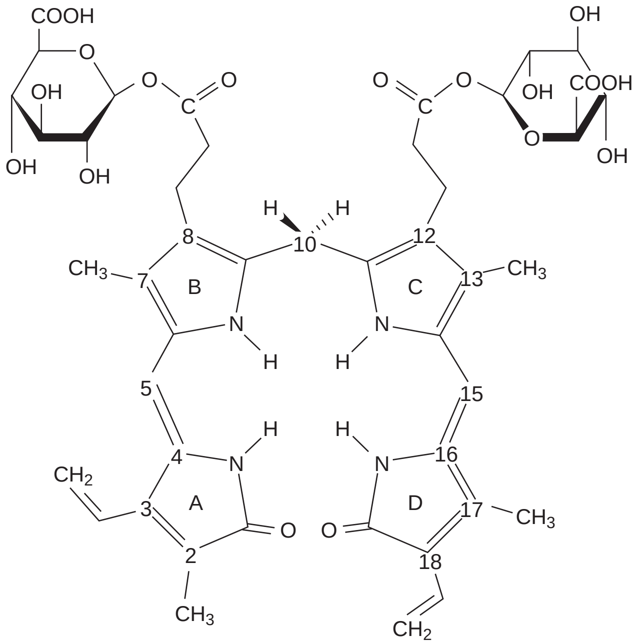

Figure 4-3 Bilirubin diglucuronide. In bilirubin monoglucuronide, only one propionic acid side chain (C-8 or C-12) is glucuronidated. *(From Gourley GR: Neonatal jaundice and disorders of bilirubin metabolism. conjugates and reduces efflux from the hepatocyte back into plasma.[33]

Bilirubin Conjugation

Inside the hepatocyte, bilirubin is conjugated with glucuronic acid[35] within the ER (microsomes). The glucuronic acid donor is uridine diphosphate glucuronic acid (UDPGA). The conjugation results in an ester linkage formed with either or both of the propionic acid side chains on the B and C pyrrole rings of bilirubin (Fig. 4-3). The enzyme responsible for this esterification is bilirubin UDP-glucuronosyltransferase (BUGT; Online Mendelian Inheritance in Man [OMIM] *191740). BUGT is distinct from the other glucuronosyltransferase isoforms which catalyze the conjugation of thyroxine, steroids, bile acids, and xenobiotics.[36] BUGT (which is the same as UGT1A1, see below) is embedded in the lipid environment of the microsomal membrane, and perturbations of this environment greatly affect in vitro measurements of BUGT activity. Since BUGT is located on the interior of the ER, the existence of a permease has been hypothesized to facilitate the transport of UDPGA from the cytosol across the lipid layers of the ER. The permease has been proposed because uridine diphosphate glucose (UDPG) is present in the cytosol in higher concentrations, yet UDPGA serves as the preferred donor for bilirubin conjugation.[37] Uridine diphosphate N-acetyl glucosamine (UDPNAG) is considered to be a natural regulator of BUGT[38] because UDPNAG increases in vitro BUGT activity threefold. The mechanism for this is unknown and could possibly involve facilitation of the permease UDPGA transporter.[39] After providing glucuronic acid for conjugation, UDP is converted to uridine and inorganic pyrophosphate by a nucleoside diphosphatase (NDPase) that is also located on the interior of the ER[40] and prevents the reverse reaction.

The specific isoform responsible for bilirubin conjugation is UGT1A1 (trivial name HUG-Br1 or BUGT, EC 2.4.1.17).[36] This is part of the UDP glycosyltransferase superfamily of enzymes encoded by the UGT gene complex on chromosome 2 that is involved with metabolism of many xenobiotic and endogenous substances. The UGT1 gene encodes several isoforms and has a complex structure consisting of four common exons (2-5) and 13 variable exons encoding different isoforms (Fig. 4-4).[41,42] At least 30 different *UGT1* mutant alleles have been described that cause Gilbert's syndrome and Crigler-Najjar (CN) syndromes I and II.[43] UGT1A1 catalyzes the formation of both bilirubin mono- and diglucuronides[44] but also metabolizes other hormones and drugs, so mutations could be involved in carcinogenesis and adverse drug reactions.[45] In normal adult humans the majority of bilirubin conjugates are excreted in the bile as bilirubin diglucuronides (approximately 80%)[46-48,49,50,51] (Fig. 4-5, middle panel). Lesser amounts of bilirubin monoglucuronides (approximately 15%) are also excreted along with very small amounts of unconjugated bilirubin (UBIL) and other bilirubin conjugates (e.g., glucose, xylose, and mixed diesters). In infants, because there is lower UGT1A1 activity, bile contains less bilirubin diglucuronide and more bilirubin monoglucuronide than the adult (Fig. 4-6, middle panel).

Bilirubin Excretion

Chromatograms represent analysis of serum (20 µl; *top*), duodenal bile (20 µl; *middle*) and stool extract (equivalent to 50 mg of wet stool; *bottom*) from a normal man. Scale of y axes varies. Serum bile pigments are almost all bilirubin. The bilirubin di- and monoglucuronides *(BDG, BMG)* that predominate in adult bile are not present in adult feces because of metabolism by intestinal bacteria. *(From Gourley GR: Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF, editors:* Liver disease in children, *ed 3, New York, 2007, Cambridge University Press.)*

membrane is canalicular multispecific organic anion transporter (cMOAT). cMOAT is a member of the ATP-binding cassette (ABC) transporter superfamily and is homologous to the multidrug resistance–associated protein (MRP2).[52,53] It is also known as ABCC2 because it is encoded by the ABCC2 gene.[54] cMOAT/MRP2/ABCC2 is involved with ATP-dependent transport across the apical canalicular membrane of a variety of endogenous compounds and xenobiotics[55] including both bilirubin mono- and diglucuronide.[56] cMOAT has previously been described as the nonbile acid organic anion transporter, the glutathione S-conjugate export pump, or the leukotriene export pump.[57] Genetic mutations which alter these ABC transporters cause diseases which include cystic fibrosis, hyperinsulinemia, adrenoleukodystrophy, multidrug resistance,[58] and, as will be discussed later in this chapter, Dubin-Johnson syndrome. This mechanism can be saturated with increasing amounts of bilirubin or bilirubin conjugates.[59-61] Many other organic anions (e.g., BSP, ICG), share this same canalicular membrane

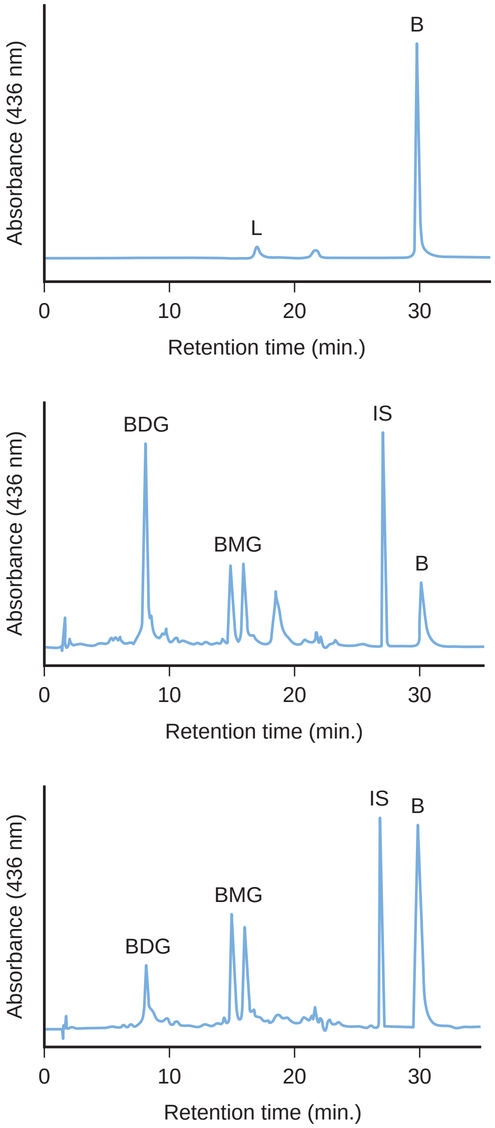

Figure 4-6 Bile pigment excretion in the newborn human as assessed by high-performance liquid chromatography. Chromatograms represent analysis of serum (20 µl; *top*) of an infant receiving phototherapy in the first week of life, and duodenal bile (20 µl; *middle*) and stool extract (equivalent to 50 mg of wet stool; *bottom*) from a normal full-term, formula-fed female infant on day 3 of life. Serum bile pigments include lumirubin *(L)*. Scale of y axes varies. Neonates lack an intestinal bacterial flora and, hence, large quantities of bilirubin di- and monoglucuronides *(BDG, BMG)* and bilirubin *(B)* are present in feces. *(From Gourley GR: Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF, editors:* Liver disease in children, *ed 3, New York, 2007, Cambridge University Press.)*

excretion mechanism.[62] Simultaneous infusions of BSP and ICG will decrease the maximal canalicular excretion of bilirubin and vice versa.[63,64] The canalicular excretion mechanism for bilirubin and BSP are different from that of bile salts. Biliary excretion of conjugated bilirubin and BSP is decreased in individuals with the Dubin-Johnson syndrome,[65] though bile salt excretion in not impaired. However, bile salt and bilirubin conjugate excretion by the canalicular membrane are not completely independent since infusion of bile salts does increase the maximal excretion of bilirubin conjugates.[66] A similar effect in seen with phenobarbital.[67] Conversely the maximal excretion of bilirubin conjugates can be decreased by cholestatic agents like estrogens and anabolic steroids.[68,69]

Under normal conditions there is evidence that bilirubin conjugates equilibrate across the sinusoidal membrane of hepatocytes resulting in small amounts of bilirubin conjugates being present in the systemic circulation.[70,71,72] If there is diminished hepatic glucuronidation of bilirubin (e.g., in the neonate), there will be a decreased amount of bilirubin conjugates present in the serum.[70,71,73] Data show that in full-term newborns there is an increase in the serum level of bilirubin diconjugates (0.55 ± 0.25% on days 2 to 4 to 1.62 ± 0.99% on days 9 to 13) which are consistent with the maturation of bilirubin glucuronidation.[74] In contrast, in premature infants less than 33 weeks' gestation, bilirubin diconjugates were very low and remained so, suggesting a more severe immaturity of the glucuronidation process.

In many pathologic circumstances, bilirubin mono- and diglucuronides are not excreted from the hepatocyte fast enough to prevent significant reflux back into the circulation. The resulting elevation of serum bilirubin conjugate levels results in the transesterification of bilirubin glucuronide with an amino group on albumin, producing a covalent bond between albumin and bilirubin.[75] This product is formed spontaneously and is known as *delta bilirubin* or *bilirubin-albumin*.[76] Similar nonenzymatic reactions have been demonstrated between albumin and various drugs.[75,77-79] Delta bilirubin is not formed in hyperbilirubinemic conditions unless there is elevation of the conjugated bilirubin fraction. Both delta bilirubin and bilirubin conjugates are direct reacting, which explains a situation that has long confounded clinicians. The direct bilirubin may continue to be elevated in patients who otherwise are recovering from a hepatic insult because the delta bilirubin formed lingers due to the long (~20 day[80]) half-life of albumin.

Enterohepatic Circulation of Bilirubin

When bilirubin conjugates enter the intestinal lumen (see Fig. 4-2), several possibilities for further metabolism arise. In adults, the normal bacterial flora hydrogenate various carbon double bonds in bilirubin to produce assorted urobilinogens (Fig. 4-7). Subsequent oxidation of the middle (C-10) carbon produces the related urobilins. Because there are a large number of unsaturated bonds in bilirubin, there are many compounds formed by reduction and oxidation of these bonds. This large family of related reduction–oxidation products of bilirubin is known as *urobilinoids*[81] and excreted in the feces and urine. Bacteria capable of producing urobilinoids include *Clostridium ramosum*,[82] *Escherichia coli, Bacteroides fragilis*,[83] *Clostridium perfringens*, and *Clostridium difficile*.[84] The conversion of bilirubin conjugates to urobilinoids is important because it blocks the intestinal absorption of bilirubin known as the *enterohepatic circulation*.[85,86] Neonates lack an intestinal bacterial flora and are more likely to absorb bilirubin from the intestine. This difference in bile pigment excretion between adults and neonates is demonstrated by comparing Figures 4-5 and 4-6 (lower panels).

Bilirubin conjugates in the intestine can also act as substrate for either bacterial[87-89] or endogenous tissue[90] β-glucuronidase. This enzyme hydrolyses glucuronic acid from bilirubin glucuronides. The UBIL produced is more rapidly absorbed from the intestine.[91] In the fetus, tissue β-glucuronidase is detectable by 12 weeks' gestation and is believed to play an important role in facilitating intestinal bilirubin absorption that enables bilirubin to be cleared via the placenta. Following birth, increased intestinal β-glucuronidase can increase the neonate's likelihood of experiencing higher serum bilirubin levels.[92] The ability of endogenous tissue β-glucuronidase to deconjugate bilirubin glucuronides has been demonstrated in germ-free animals.[93] Breastmilk can contain high levels of β-glucuronidase, and it has been suggested that this is one factor related to the higher jaundice levels seen in breastfed infants.[94] Feeding specific nutritional ingredients that inhibit β-glucuronidase, such as hydrolyzed casein or L-aspartic acid[95] have been shown to result in increased fecal bilirubin excretion and lower levels of jaundice.[96]

DIAGNOSIS OF HYPERBILIRUBINEMIA

Jaundice and icterus both refer to the yellow discoloration of the tissues (skin, sclerae, etc.) caused by deposition of bilirubin. *Jaundice*, from the French *jaune* means yellow. *Icterus* is derived from the Greek word for jaundice *(ikteros)*. Jaundice is a sign that hyperbilirubinemia exists (i.e., total serum bilirubin greater than approximately 1.4 mg/dL after 6 months of age, 1 mg/dL = 17 μmol/L). The degree of jaundice is directly related to the level of serum bilirubin and the amount of bilirubin deposited in the extravascular tissues. Hypercarotenemia, occasionally mistaken for jaundice, can impart a yellow hue to the skin, but the sclerae remain white. There are many conditions associated with neonatal jaundice. Some of these states are so commonly recognized as to be termed *physiologic*. Alternatively jaundice can be a sign of severe disease.

Total Serum Bilirubin Measurements

Measurement of the total serum bilirubin concentration allows quantitation of jaundice. Such measurements are very common in the newborn nursery and in one study were made at least once in 61% of term newborn infants.[97] Two components of total serum bilirubin can be routinely measured in the clinical laboratory: conjugated bilirubin ("direct" reacting, because in Van den Bergh's test, color development takes place directly without adding methanol), and UBIL ("indirect" fraction). Although the terms

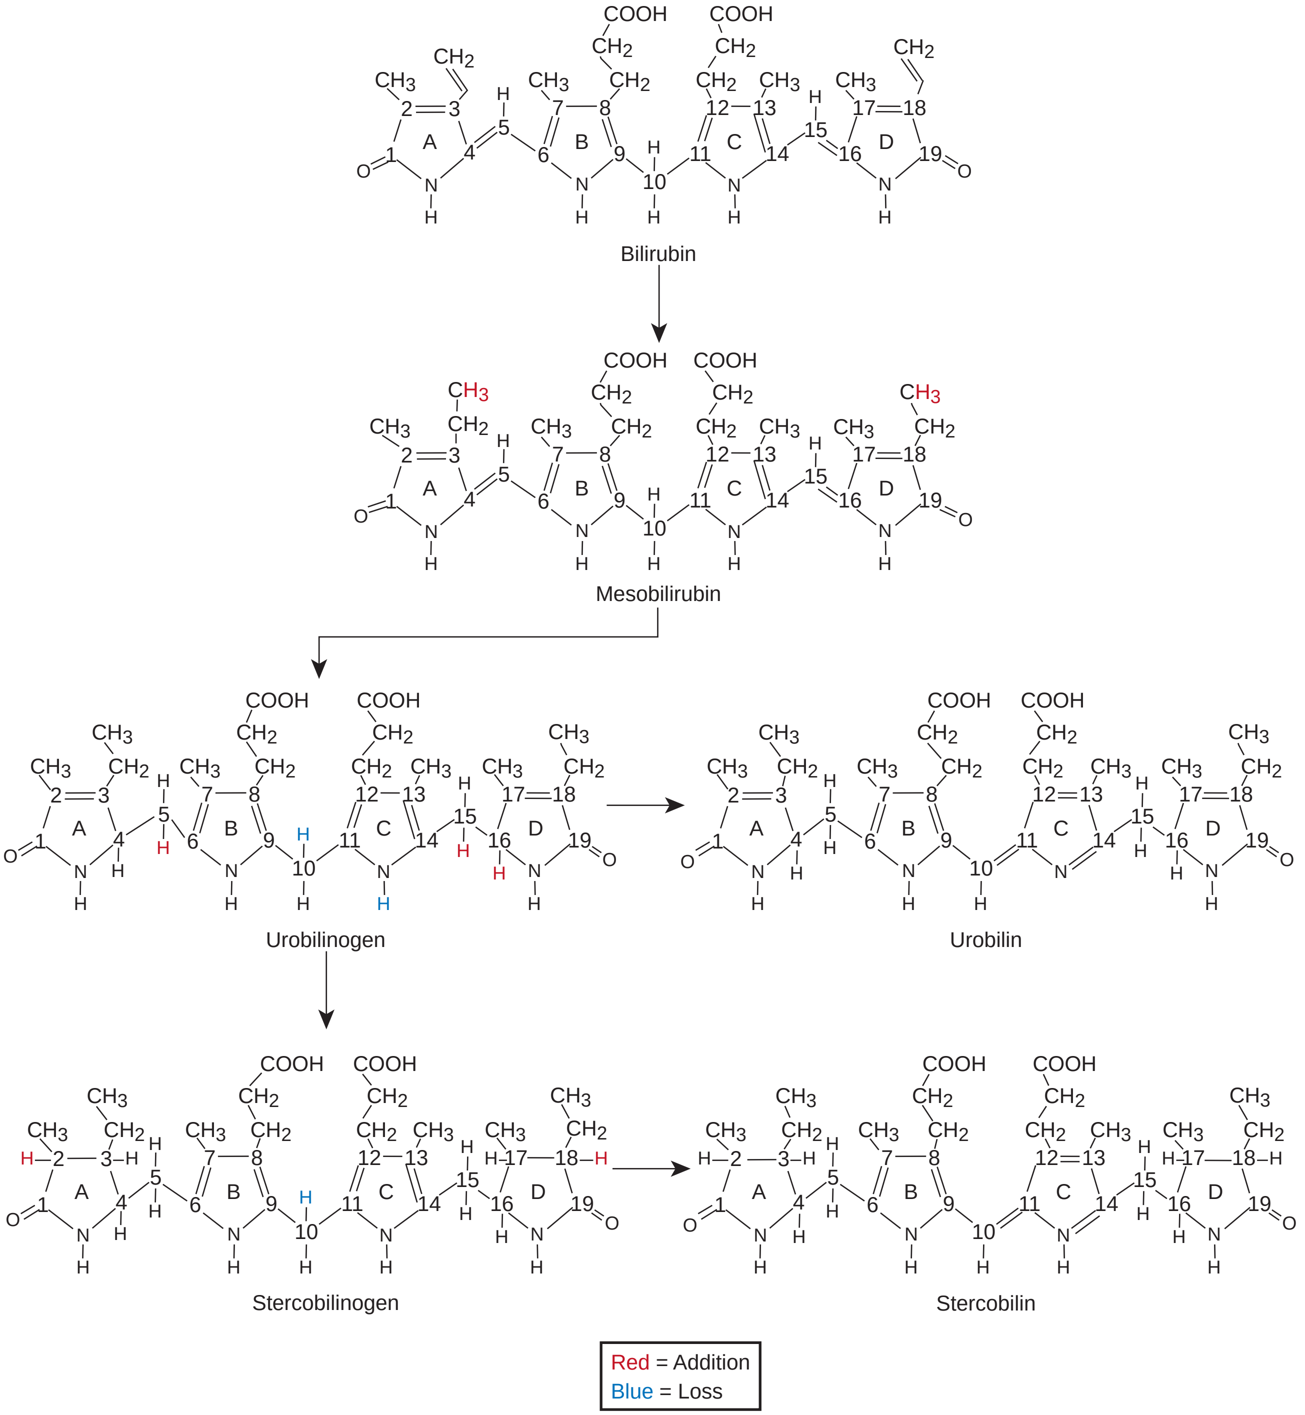

Figure 4-7 The reduction and oxidation of bilirubin to a family of related compounds known collectively as *urobilinoids*. Only several examples are given of this much larger family. *(From Gourley GR: Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF, editors:* Liver disease in children, *ed 3, New York, 2007, Cambridge University Press.)*

direct and *indirect* are often used equivalently with conjugated and UBIL, this is not quantitatively correct because the direct fraction includes both conjugated bilirubin and albumin-bound delta bilirubin.[98] Elevation of either of these fractions can result in jaundice. There is a long history of undesirable variability in the measurement of serum bilirubin fractions.[99,100] One problem is the ditaurobilirubin (DTB) content of standards set by the College of American Pathologists (CAP).[100] The DTB influences the result variably because of protein matrix differences related to the specific bilirubin measurement used. This has prompted the suggestion that standards consist of human serum enriched solely with UBIL rather than bovine serum containing a mixture of UBIL and DTB.[101] The automated laboratory methods now used to measure serum bilirubin have been reviewed elsewhere.[98,102-104] The Jendrassik-Grof procedure is the method of choice for total bilirubin measurement, though this method also has problems.[105] When the total serum bilirubin level is high, factitious elevation of the direct fraction has been reported.[106] Three newer methods have been developed which can more accurately determine the various bilirubin fractions (unconjugated, monoconjugated, diconjugated, and albumin-bound or delta): high-performance liquid chromatography (HPLC),[107] multilayered slides,[108,109] and use of bilirubin oxidase.[110] HPLC analysis is superior and used as the gold standard,[111,112] but it is too expensive and time consuming for the clinical laboratory.[98] HPLC analysis of serum from normal human neonates in the first 4 days of life[113] showed unconjugated and conjugated bilirubin levels rose in parallel with the conjugated fraction, making up only 1.2% to 1.6% of total pigment (3.6% in adults). Although the absolute concentration of conjugates was 2 to 6 times higher in neonates, only 20% were diconjugates (54% in adults). These sensitive HPLC data are consistent with the increased bilirubin production and relatively deficient glucuronidation seen in the neonate. Analysis with automated multilayered slide technology (VITROS, Johnson & Johnson) used in many clinical laboratories allows measurement of specific conjugated and UBIL fractions without inclusion of delta bilirubin. The conjugated bilirubin measurement is an earlier indicator of relief from biliary cholestasis than is direct bilirubin because of the long half-life of delta bilirubin.[114] A comparison of the bilirubin oxidase method concluded that determinations of total bilirubin in neonatal serum were not advanced by this method.[115]

Newer methods of total bilirubin measurement (Twin Beam, Ginevri, Rome, Italy; ABL 735, Radiometrer, Copenhagen, Denmark; Roche OMNI S, Roche Diagnostics, Graz, Austria) using nonenzymatic photochemical analysis offer the convenience of bilirubin quantitation outside of a core lab setting (i.e., blood gas analyzer in the nursery) using a smaller blood sample than traditional serum analysis. However, these measurements must be interpreted with caution because the instruments tend to underestimate the total bilirubin concentration at greater than 15 mg/dL.[116]

There are conflicting data regarding the accuracy of capillary versus venous serum bilirubin levels.[117,118] However, as Maisels has pointed out, the literature regarding kernicterus, phototherapy, and exchange transfusion is based on bilirubin measurements in capillary samples.[119]

Transcutaneous Bilirubinometry

Noninvasive methods to measure jaundice levels have been shown to be useful in neonates. Current commercially available methods include the BiliChek (Respironics, Pittsburgh, Pennsylvania)[111,112] and the Minolta/Hill-Rom Air-Shields Transcutaneous Jaundice Meter 103 (Air-Shields, Hatboro, Pennsylvania).[120] The technique utilizes principles of reflectance spectrophotometry, has been validated against both HPLC and clinical laboratory measures,[111,112] and is advocated by the American Academy of Pediatrics (AAP).[121] The device is touched to the skin in a painless manner with the immediate resulting point-of-care measurement of transcutaneous bilirubin (TcB). Significant TcB levels (e.g., greater than 13 mg/dL) should prompt measurement of a serum or plasma bilirubin level. Some suggest that the yellow color of the skin is a better risk indicator of bilirubin-dependent brain damage than is the serum bilirubin level.[122] A less expensive[123] method useful in assessing jaundice[124,125] utilizes a plexiglass color chart pressed against the baby's nose (Ingram icterometer, Thos. A. Ingram and Co. Ltd, Birmingham, England).

TOXICITY OF UNCONJUGATED HYPERBILIRUBINEMIA

Kernicterus

Reviews of neonatal bilirubin toxicity have been published elsewhere.[1,126,127] Kernicterus (German: *kern*: nucleus; Latin: *icterus*: yellow) is the neuropathologic finding associated with severe unconjugated hyperbilirubinemia and is named for the yellow staining of certain regions of the brain, particularly the basal ganglia, hippocampus, cerebellum, and nuclei of the floor of the fourth ventricle.[126,128] Acute clinical findings associated with kernicterus, termed *acute bilirubin encephalopathy,* include sluggish Moro reflex, opisthotonos, retrocollis, hypotonia, vomiting, high-pitched cry, hyperpyrexia, seizures, paresis of gaze ("setting sun sign"), oculogyric crisis, and death. Long-term findings (chronic bilirubin encephalopathy) include spasticity, choreoathetosis, dental enamel dysplasia of the desiduous teeth, and sensorineural hearing loss. Milder forms of bilirubin encephalopathy include cognitive dysfunction and learning disabilities.[129,130] In 17-year-old males, the risk of having an IQ score less than 85 was found to be significantly higher among full-term subjects with neonatal serum bilirubin levels above 20 mg/dL.[131] The mechanisms of bilirubin cytotoxicity are complex and have been reviewed elsewhere.[126,127,132-134] Though the neonatal period is the most common time for bilirubin-related brain damage, the neurotoxicity of bilirubin has also been documented in older children and adults with CN syndrome, type I.[135,136]

The absolute level of serum bilirubin has not been a good predictor of the risk of bilirubin encephalopathy. However, it has long been known that kernicterus is likely with serum UBIL levels greater than 30 mg/dL and unlikely with levels less than 20 mg/dL.[137-139] In one study, 90% of the patients who had a bilirubin level greater than 35 mg/dL either died or had cerebral palsy or physical retardation.[139] Alternatively, no developmental retardation was found in 129 infants with bilirubin levels less than 20 mg/dL. Albumin concentration is an important variable because of the high affinity binding with bilirubin, and the ratio of bilirubin to albumin is a risk factor that has been included in the most recent AAP guidelines.[121] Drugs and organic anions also bind to albumin and can displace bilirubin, thereby increasing the free bilirubin which can diffuse into cells and cause toxicity,[140,141] such as when sulfisoxazole was given to premature infants.[142] Walker has reviewed neonatal bilirubin toxicity and drug-induced bilirubin displacement.[132] In recent years there has been a reemergence of kernicterus.[127] While it has been acknowledged that total serum bilirubin may not be the most important factor related to risk, there are, at present, no other generally accepted tests (e.g., albumin saturation, reserve bilirubin binding capacity, or free bilirubin concentration) which are more helpful in identifying infants at risk for bilirubin encephalopathy. Recently the basics of bilirubin–albumin binding and neonatal jaundice have been reviewed by Ahlfors and Wennberg.[143] Additionally, Ahlfors and colleagues have recently described how to use zone fluidics (the precisely controlled physical, chemical, and fluid-dynamic manipulation of zones of miscible and immiscible fluids and suspended solids in narrow bore conduits to accomplish sample conditioning and chemical analysis) to measure free bilirubin and overcome some of the existing problems with unbound (free) bilirubin measurement.[144] Wennberg and colleagues speculate that enhanced sensitivity and specificity of newer methods of free bilirubin measurement will provide for the establishing of improved risk threshold for kernicterus and therefore reduce unnecessary aggressive intervention (i.e., exchange transfusion) and its associated cost and morbidity.[145]

Another approach aimed at measuring early changes in the CNS caused by bilirubin has assessed brainstem auditory evoked potentials (BAEP).[146,147] Abnormalities in the BAEP have been demonstrated in jaundiced infants and shown to improve after exchange transfusion.[148,149] Data have shown that even moderate hyperbilirubinemia (mean ± SD: 14.3 ± 2.8 mg/dL) affects the BAEP, specific components of the Brazelton Neonatal Behavioral Assessment Scale,[150] and cry characteristics.[151]

Another reported toxicity of neonatal jaundice relates not to the CNS of the jaundiced infant, but rather to the attitude of that infant's parents. Mothers of jaundiced infants more frequently exhibit behavior suggesting the "vulnerable-child syndrome,"[152,153] including inappropriate visits to the physician because of unrealistic perceptions of illness, separation difficulties, and early termination of breastfeeding. Another study showed, however, that hyperbilirubinemia and/or phototherapy during the neonatal period are not associated with impaired mother–child attachment after the first year of life.[154]

NONPATHOLOGIC UNCONJUGATED HYPERBILIRUBINEMIA

Physiologic Jaundice

The term *physiologic jaundice* has been used to describe the frequently observed jaundice in otherwise completely normal neonates. However, physiologic jaundice is merely the result of a number of factors involving increased bilirubin production and decreased excretion.

Jaundice should always be considered to be a sign of a possible disease and not routinely explained as physiologic. Specific characteristics of neonatal jaundice to be considered abnormal until proven otherwise include: (1) development before 36 hours of age; (2) persistence beyond 10 days of age; (3) serum bilirubin greater than 12 mg/dL at any time; (4) elevation of the direct bilirubin (direct bilirubin greater than 1 mg/dL if the total bilirubin is less than 5 mg/dL, or direct bilirubin greater than 20% of the total bilirubin if the total bilirubin is greater than 5 mg/dL[155]). The physiologic immaturity of premature infants is associated with both higher peak serum bilirubin levels and pathologic conditions.[156]

In general, infants are not jaundiced at the moment of birth, due to the impressive ability of the placenta to clear bilirubin from the fetal circulation. However, within the next few days most if not all infants will develop elevated serum bilirubin levels (greater than 1.4 mg/dL), with clinical jaundice evident when the total bilirubin level exceeds 2 to 5 mg/dL. As the serum bilirubin rises, the skin becomes more jaundiced in a cephalocaudal manner.[157] Kramer found the following serum indirect bilirubin levels as jaundice progressed: head and neck: 4 to 8 mg/dL; upper trunk: 5 to 12 mg/dL; lower trunk and thighs: 8 to 16 mg/dL; arms and lower legs: 11 to 18 mg/dL; palms and soles: greater than 15 mg/dL.[158] Hence when the bilirubin was greater than 15 mg/dL, the entire body was icteric. However, darker skin tones can make jaundice difficult to estimate visually.[121] Jaundice is best observed by blanching the skin with gentle digital pressure under well-illuminated (white light) conditions. At least one third of infants develop visible jaundice. A combined analysis of several large studies involving thousands of infants during the first week of life showed that moderate jaundice (bilirubin greater than 12 mg/dL) occurs in at least 12% of breastfed infants and 4% of formula-fed infants, while severe jaundice (greater than 15 mg/dL) occurs in 2% and 0.3% of these respective feeding groups.[159]

There are a number of epidemiologic risk factors related to neonatal jaundice that have been reviewed elsewhere.[121,160-162] Risk factors include male gender, low birth weight, prematurity, polycythemia, certain ethnicities (Asian, Native American, Greek), maternal medications (e.g., oxytocin, promethazine hydrochloride), premature rupture of the membranes, increased weight loss after birth, delayed meconium passage, breastfeeding, and neonatal infection. Delivery with the vacuum extractor increases the risk of cephalohematoma and neonatal jaundice.[163] Data suggest pancuronium is associated with an increased risk of hyperbilirubinemia.[164] There is a significant correlation between umbilical cord serum bilirubin level and subsequent hyperbilirubinemia.[165,166] Maternal serum bilirubin level at the time of delivery and transplacental bilirubin gradient also correlate positively with neonatal serum bilirubin concentrations.[166] Factors associated with decreased neonatal bilirubin levels[121,167] include African race, exclusive formula feeding, gestational age 41 weeks, maternal smoking, and certain drugs given to the mother (e.g., phenobarbital).

Breastfeeding and Jaundice

Breastfeeding has been clearly identified as a factor related to neonatal jaundice,[159] and this subject has been reviewed elsewhere.[168,169] Breastfed infants have been shown to have significantly higher serum bilirubin levels than formula-fed infants on each of the first 5 days of life,[170] and this unconjugated hyperbilirubinemia can persist for weeks[171] to months.[172,173] Jaundice during the first week of life is sometimes described as *breastfeeding jaundice* in order to differentiate it from breastmilk jaundice syndrome, which occurs after the first week of life.[174-176] The former is frequently associated with inadequate breastmilk intake, whereas the latter generally occurs in otherwise thriving infants. There is probably overlap between these conditions and physiologic jaundice. Early reports linking breastmilk and neonatal jaundice with a steroid (pregnane-3(α),20(β)-diol) in some milk samples[177] have not been confirmed by more recent larger studies utilizing more sensitive methods.[178] There are also conflicting data regarding efforts to attribute this jaundice to increased lipase activity in the breastmilk, resulting in elevated levels of free fatty acids, which could inhibit hepatic glucuronosyltransferase.[179] It has been suggested that the enterohepatic circulation of bilirubin can be facilitated by the presence of β-glucuronidase[92,180] or some other substance in human milk.[181] Other factors possibly related to jaundice in breastfed infants include caloric intake, fluid intake, weight loss, delayed meconium passage, intestinal bacterial flora, and inhibition of bilirubin glucuronosyltransferase by an unidentified factor in the milk.[94] Lascari suggests that a healthy breastfed infant with unconjugated hyperbilirubinemia, normal hemoglobin concentration, reticulocyte count, blood smear, no blood group incompatibility, and no other abnormalities on physical examination may be presumed to have early breastfeeding jaundice.[175] Because there is no specific laboratory test to confirm a diagnosis of breastmilk jaundice, it is important to rule out treatable causes of jaundice before ascribing the hyperbilirubinemia to breastmilk. Some infants with presumed breastmilk jaundice exhibit elevated serum bile acid levels suggesting mild hepatic dysfunction or cholestasis,[182] though in general this is not the case. Breastfed infants who are fed specific nutritional ingredients, such as L-aspartic acid, that inhibit β-glucuronidase[95] excrete more fecal bilirubin and have lower levels of jaundice[96] than breastfed infants who receive no supplements. No commercial preparations of these specific ingredients are presently available.

DISORDERS OF PATHOLOGIC UNCONJUGATED HYPERBILIRUBINEMIA

Disorders of Production

Isoimmunization

The most common cause of severe early jaundice is fetal–maternal blood group incompatibility with resulting isoimmunization (see Chapter 3). Maternal immunization develops when erythrocytes leak from fetal to maternal circulation. Fetal erythrocytes carrying different antigens are recognized as foreign by the maternal immune system that forms antibodies against them (maternal sensitization). These antibodies (IgG immunoglobulins) cross the placental barrier into the fetal circulation and bind to fetal erythrocytes. In Rh incompatibility, sequestration and destruction of the antibody-coated erythrocytes takes place in the reticuloendothelial system of the fetus. In ABO incompatibility, hemolysis is intravascular, complement mediated, and usually not as severe as in Rh disease.[183] Significant hemolysis can also result from incompatibilities between minor blood group antigens (e.g., Kell).[184] Although hemolysis is predominantly associated with elevation of UBIL, the conjugated fraction can also be elevated.[185] Any type of isoimmune hemolytic disease is a risk factor for kernicterus.[121]

Rh incompatibility problems do not usually develop until the second pregnancy, thus prenatal blood typing and serial testing of Rh-negative mothers for the development of Rh antibodies provide important information to guide possible intrauterine care. If maternal Rh antibodies develop during pregnancy, potentially helpful measures include serial amniocentesis (with bilirubin measurement),[186,187] ultrasound assessment of the fetus,[188,189] intrauterine transfusion,[190,191] and premature delivery. The prophylactic administration of anti-D gamma globulin[192] has been most helpful in preventing Rh sensitization. The newborn infant with Rh incompatibility presents with pallor, hepatosplenomegaly, and a rapidly developing jaundice in the first hours of life. In severe cases the infant may be born with generalized edema (fetal hydrops). Laboratory findings in the neonate's blood include reticulocytosis, anemia, a positive direct Coombs' test, and a rapidly rising serum bilirubin level. Conjugated hyperbilirubinemia is occasionally observed in Rh erythroblastosis, particularly when intrauterine transfusions have been used.[113] This may be the result of exceeding the hepatic excretory capacity. Alternatively, cholestasis may also result from hepatic congestion from extramedullary erythropoiesis and heart failure, or tissue hypoxia resulting from reduced hepatic blood flow and anemia.[193] Cholestasis in infants with erythroblastosis fetalis may also be exacerbated by secondary complications, including biliary obstruction, sepsis, or hepatic failure.[194]

Therapeutic intervention with phototherapy and consideration of exchange transfusion should be initiated at lower serum bilirubin concentrations in infants with isoimmune hemolysis, and intravenous gamma-globulin has been shown to reduce the need for exchange transfusions in Rh and ABO hemolytic disease.[121] Serum bilirubin measurements should be obtained as frequently as every 4 hours to establish the rate of increase and to assess the effect of therapy. Exchange transfusions may be performed as emergency procedures in severe cases almost immediately after delivery in order to treat anemia and heart failure.

In contrast to Rh incompatibility, ABO incompatibility usually presents clinically with the first pregnancy. ABO hemolytic disease is largely limited to blood group A or B infants born to group O mothers.[195] ABO hemolytic disease is relatively rare in type A or B mothers. Development of jaundice is not as rapid as with Rh disease, and a serum bilirubin greater than 12 mg/dL on day 3 of life would be typical. Laboratory abnormalities include reticulocytosis (greater than 10%) and a weakly positive direct Coombs' test, though this is sometimes negative. Anti-A or anti-B antibodies may be seen in the serum of the newborn if examined within the first few days of life, before they rapidly disappear. Spherocytes are the most prominent feature seen in the peripheral blood smear with ABO incompatibility.

Erythrocyte Enzymatic and Structural Defects

A number of specific abnormalities of the red blood cell can result in neonatal jaundice, including hemoglobinopathies and red blood cell membrane and enzyme defects. Hereditary spherocytosis (see Chapter 16) can be a neonatal problem with significant hemolysis and present with a rising bilirubin level and a falling hematocrit.[196] A family history of spherocytosis, anemia or early gallstone disease (before age 40) is helpful in suggesting this diagnosis. The characteristic spherocytes seen in the peripheral blood smear may be impossible to distinguish from those seen with ABO hemolytic disease. Other erythrocyte conditions associated with neonatal jaundice include drug-induced hemolysis, deficiencies of the erythrocyte enzymes (glucose 6-phosphate dehydrogenase [G6PD] deficiency[197,198] [see Chapter 17], pyruvate kinase deficiency, and others) (see Chapter 18), and hemolysis induced by vitamin K or bacteria. Recent studies of G6PD activity in African-American neonates suggest that hemolysis is neither the predominate factor in the pathogenesis of hyperbilirubinemia, nor is it alone predictive of hyperbilirubinemia,[199] though African-American male neonates may be at higher risk for hyperbilirubinemia, particularly if breastfed and premature.[200] This emphasizes the important relationship between bilirubin excretion and serum bilirubin concentration.[201] α-thalassemia (see Chapter 21) can result in severe hemolysis and lethal hydrops fetalis.[202] β-thalassemia (see Chapter 21) may also present with hemolysis and severe neonatal hyperbilirubinemia.[203] There are a wide variety of clinical findings associated with the thalassemias, extending from profound intrauterine hydrops and death, to mild neonatal jaundice and anemia, to no jaundice or anemia. Southeast Asian ovalocytosis (see Chapter 16) has been associated with severe hyperbilirubinemia.[204] These red blood cell abnormalities are more likely to result in hyperbilirubinemia in the presence of Gilbert's syndrome as described later in this chapter.

Drugs or other substances responsible for hemolysis can be passed to the fetus across the placenta or to the neonate via breastmilk. Induction of labor with oxytocin has been shown to be associated with neonatal jaundice. There is a significant association between hyponatremia and jaundice in infants of mothers who received oxytocin to induce labor.[205,206] The vasopressin-like action of oxytocin prompts electrolyte and water transport, and it is suggested that the erythrocyte swells, and increased osmotic fragility and hyperbilirubinemia can result. Steroid administration at the initiation of oxytocin and 4 hours later may be helpful in preventing this hyperbilirubinemia.[207]

Infection

Bacterial sepsis increases bilirubin production through initiation of erythrocyte hemolysis or via endotoxin-mediated reduction of canalicular bile secretion, resulting in a combination of conjugated and unconjugated hyperbilirubinemia. However, hyperbilirubinemia is rarely the only manifestation of bacteremia or sepsis,[208] and some data suggest sepsis may result in lower peak levels of UBIL through consumption of bilirubin as an antioxidant in response to oxidant production by phagocytic cells.[209]

Sequestration

Extravascular blood within the body can be rapidly metabolized to bilirubin by tissue macrophages. Examples of this increased bilirubin production include cephalohematoma, ecchymoses, petechiae, and hemorrhage. Although the diagnosis can often be made on physical examination, occult intracranial, intestinal, adrenal, or pulmonary hemorrhage can also produce hyperbilirubinemia. Similarly, swallowed blood can be converted to bilirubin by the HO of intestinal epithelium. From a red sample of bloody gastric contents, meconium, or stool, the Apt test can be used to distinguish blood of maternal or infant origin because of differences in alkali-resistance between fetal and adult hemoglobin;[210,211] however, this test has low sensitivity and poor reproducibility, and an HPLC method has been shown to be superior.[212]

Polycythemia

Polycythemia can cause hyperbilirubinemia because the absolute increase in red cell mass results in elevated bilirubin production through normal rates of erythrocyte breakdown. A number of mechanisms may result in neonatal polycythemia (usually defined by venipuncture hematocrits greater than 65%) as reviewed by Werner.[213] Maternal–fetal transfusion during peripartum placental separation, a delay in umbilical cord clamping at birth, and twin–twin transfusion syndrome are all commonly encountered causes of polycythemia. Similarly, intrauterine hypoxia and maternal diseases such as diabetes mellitus can result in neonatal polycythemia. Therapy for symptomatic polycythemia is partial exchange transfusion, though therapy for asymptomatic polycythemia remains controversial.[214]

Disorders of Conjugation

The disorders described in this section, summarized in Tables 4-1 and 4-2, are those in which there is a primary abnormality in bilirubin metabolism without other liver disease.[215] The disorders can best be understood in the context of the normal pathway in which bilirubin is cleared from the circulation (see Fig. 4-2). Defects in these metabolic steps are responsible for the disorders to be described in the final section of this chapter.

Gilbert's Syndrome

Clinical Presentation. Gilbert's syndrome (GS) (OMIM #143500) was first described in 1901 by Gilbert and Lereboullet.[216] It is characterized by a hereditary chronic or recurrent, mild unconjugated hyperbilirubinemia with otherwise normal liver function tests (for reviews, see[217-219]). The serum UBIL elevation is variable and usually ranges from 1 to 4 mg/dL (17 µmol/L = 1 mg/dL). Frequently patients are first identified when an elevated serum bilirubin is found on screening blood chemistry or

TABLE 4-1 Comparison of Disorders of Unconjugated Hyperbilirubinemia

		Gilbert's Syndrome	**Crigler-Najjar Type I**	**Crigler-Najjar Type II**
Prevalence		3%	Rare	Rare
Inheritance		Autosomal dominant or recessive	Autosomal recessive	Autosomal recessive, rarely dominant
Genetic Defect		UGT1A1 gene	UGT1A1 gene	UGT1A1 gene
Hepatocyte Defect Site		Microsomes +/– plasma membrane	Microsomes	Microsomes
Deficient Hepatocyte Function		Glucuronidation +/– uptake	Glucuronidation	Glucuronidation
BUGT Activity		5%-53% of controls	Severely decreased	2%-23% of controls
Hepatocyte Uptake		Decreased in 20%-30%	Normal	Normal
Serum Total Bilirubin Level (mg/dL)		0.8-4.3	15-45	8-25
Serum Bilirubin Decrease with Phenobarbital (%)		70	0	77
HPLC Serum Bilirubin Composition				
	(Normal %)			
Unconjugated	(92.6)	98.8	~100	99.1
Diglucuronide	(6.2)	1.1	0	0.6
Monoglucuronide	(0.5)	0	0	0
Bile Bilirubin Conjugates

mild jaundice (perhaps only scleral icterus) is noted during a period of fasting associated with a nonspecific viral illness or religious activities.[220] Icteric plasma from a blood donor may suggest GS.[221] Alternatively, hyperbilirubinemia post liver transplant may be a sign that the donor had GS.[222-225] GS in normal adults is generally associated with no negative implications for health or longevity; however, a large variety of common symptoms have been reported by patients with GS.[226,227] These symptoms include vertigo headache, fatigue, abdominal pain, nausea, diarrhea, constipation, and loss of appetite. The possible relationship of these symptoms to GS was evaluated in a group of 2395 Swedish subjects.[228] The only symptom that was more common in GS was diarrhea in males aged 57 to 67 years. The authors suggested that this was most likely type I error because of the large number of comparisons made and concluded that there was no higher prevalence of symptoms associated with GS. There are limited reports suggesting that GS is a risk factor for chronic fatigue syndrome.[229,230]

In two large surveys of normal individuals, approximately 3% of the population had serum bilirubin levels greater than 1 mg/dL.[231,232] If the normal upper limit of serum bilirubin is defined as 1.4 mg/dL, then there is a strong male predominance (approximately 4:1). This finding might be related to the observation that females clear bilirubin better than males.[233] GS may be inherited in either an autosomal dominant[234-237] or recessive[238] fashion.

Although GS is a congenital disorder, it rarely becomes clinically apparent until after puberty. The reasons for this are unknown but have been suggested to be related to the hormonal changes of puberty. Steroid hormones can suppress hepatic bilirubin clearance.[69] During pregnancy, increased estrogen levels are associated with impaired clearance of exogenous bilirubin.[239] Gonadectomy has been shown to alter BUGT activity.[240] Odell speculated that some infants with nonhemolytic neonatal jaundice are manifesting GS.[241] Use of genetic markers (see below) has allowed investigation of the role GS plays in neonatal jaundice. Individuals carrying such markers have been shown to have a more rapid rise in their jaundice levels during the first 2 days of life,[242] a predisposition to prolonged or severe neonatal hyperbilirubinemia,[243-245] variably increased jaundice when the GS polymorphism occurs with pyloric stenosis[246,247] or is coinherited with hematologic abnormalities such as G6PD deficiency,[201,248] β-thalassemia,[248-251] or hereditary spherocytosis.[252] Thus studies from several different parts of the world indicate that GS, as detected by

TABLE 4-2 Comparison of Disorders of Conjugated Hyperbilirubinemia

	Rotor's Syndrome	Dubin-Johnson Syndrome
Prevalence	Rare	Rare
Inheritance	Autosomal recessive	Autosomal recessive
Genetic Defect	SLCO1B1/ SLCO1B3 gene	cMOAT/MRP2/ ABCC2 gene
Hepatocyte Defect Site	GST	Apical canalicular membrane
Deficient Hepatocyte Function	Intracellular binding of bilirubin and conjugates	Cannalicular secretion of bilirubin conjugates
Brown-Black Liver	No	Yes
Serum Total Bilirubin Level (mg/dL)	2-7	1.5-6
Serum Conjugated Bilirubin (%)	>50	>50
Other Routine Liver Function Tests	Normal	Normal
Oral Cholecystogram	Usually visualizes	Usually does not visualize
^{99m}Tc- HIDA Cholescintigraphy: Liver Gallbladder	 Poor to no visualization Poor to no visualization	 Intense, prolonged visualization Delayed or no visualization
BSP Clearance Test	Serum BSP levels elevated (delayed clearance)	Serum BSP levels normal at 45 min, but elevated at 90-120 min
ICG Clearance Test	Delayed clearance	Normal
Response to Estrogens or Pregnancy	No change	Increased jaundice
Total Urinary Coproporphyrin Excretion (Isomers I + III)	2.5-5 times increased	Normal
Urinary Coproporphyrin Isomer I Composition (%) (Normal = 25%)	Usually <80% of total	>80% of total
Prognosis	Benign (asymptomatic)	Benign (occasional abdominal complaints; probably incidental)

UGT1A1 analysis, does play some role in neonatal jaundice. Kaplan *et al* noted that, in their study,[201] neither G6PD deficiency nor the GS type UDPGT1 promoter polymorphism (also known as *UGT1A1*28*) alone increased the incidence of hyperbilirubinemia, but both in combination did (Fig. 4-8). They speculated that this gene interaction may serve as a paradigm of the interaction of benign genetic polymorphisms in the causation of disease, in other words, it may take two genetic abnormalities to produce disease symptoms. Numerous studies indicate the increased risk of cholelithisis in patients with GS.

Pathophysiology. GS is a heterogeneous group of disorders all of which share at least a 50% decrease in hepatic BUGT activity.[253-256] Based on plasma clearance of other organic anions (BSP and ICG) that share the same hepatocyte uptake receptor carrier, there appear to be at least four subtypes of GS.[257,258] In GS type I, clearance of BSP and ICG are normal. In GS type II there is delayed BSP clearance, but ICG clearance is normal. Because BSP uptake is normal in type II, delayed clearance must be related to subsequent intrahepatic metabolism or canalicular excretion.[259] In GS type III, clearance of both BSP and ICG are delayed. The delay in the initial rate of disappearance from the plasma suggests a defect in uptake at the hepatocyte plasma membrane.[259] Those with GS type IV have delayed uptake of ICG but not BSP. Thus some individuals with GS have delayed uptake of bilirubin into the hepatocyte, others have delayed biotransformation, and others demonstrate both abnormalities.[51,260-262] Immunohistochemical staining for UGT shows a clear reduction throughout the hepatic lobule in specimens from individuals with GS, when compared to normals.[263]

The elucidation of the structure of the *UGT1* gene, which encodes human bilirubin, phenol and other UDP-glucuronosyltransferase isozymes[264,265] led to the discovery of *UGT1A1* mutations or polymorphisms associated with GS. In Caucasian populations, the homozygous

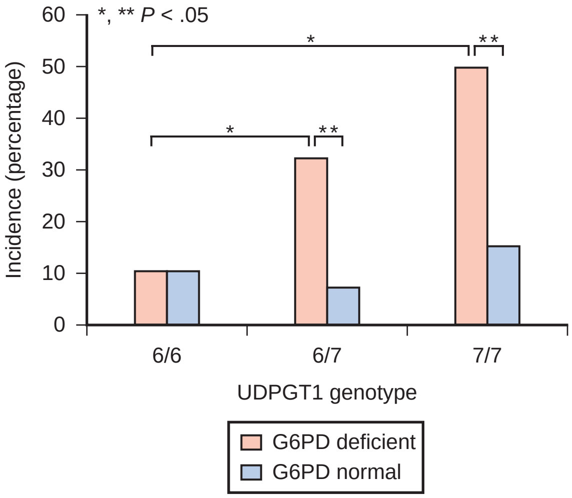

Figure 4-8 Incidence (percentage) of hyperbilirubinemia (serum total bilirubin ≥257 μmol/liter) in G6PD-deficient neonates and normal controls, stratified for the three genotypes of the UGT1A1 promoter. *(From Kaplan M, Renbaum P, Levy-Lahad E, et al: Gilbert syndrome and glucose-6-phosphate dehydrogenase deficiency: a dose-dependent genetic interaction crucial to neonatal hyperbilirubinemia.* Proc Natl Acad Sci U S A *94:12128–32, 1997.)*

finding of an additional TA repeat in the promoter region, or so called TATA box (i.e., $[TA]_7TAA$, rather than $[TA]_6TAA$) of the *UGT1A1* gene has been shown to be a necessary, though not sufficient, condition for GS.[266-268] Individuals who are heterozygous for seven TA repeats have significantly higher serum bilirubin levels than the homozygous wild type six repeats.[266] In Asian populations, the $(TA)_7TAA$ mutation is relatively rare,[269] but several different *UGT1A1* mutations have been associated with GS.[237,270,271] These Asian mutations involve exon one of the *UGT1A1* gene, rather than the TATA promoter region. One of the most common mutations in Asians, a Gly71Arg mutation in exon 1, has also linked GS and severe neonatal hyperbilirubinemia.[244] It has been reported that although within Caucasians promoter TA repeat number and bilirubin level are strongly positively correlated, in other ethnic groups (e.g., Africans, where two other variants, $[TA]_5$ and $[TA]_8$, have been identified) there is a negative correlation.[272] Rarely the $(TA)_8$ variant has been reported in Caucasians,[273] thus the ethnic implications of these genetic polymorphisms of the *UGT1A1* gene require further analysis.

Although decreased hepatic BUGT activity is universal in GS, there is poor correlation between measured enzyme activity in liver and serum bilirubin level.[274] This may be explained by the increased bilirubin production associated with the decreased red cell half-life seen in as many as 40% of patients with GS.[236,262] While early authors[254,256] concluded that there was little or no induction of BUGT following administration of phenobarbital, more recent work has revealed that, in fact, phenobarbital does increase UGT1A1 activity via a phenobarbital-responsive enhancer module (PBREM) of the *UGT1A1* promoter region[275] and that such polymorphisms could represent an additional risk factor for GS.[276]

Related to the decreased BUGT activity is the observation that duodenal bile from individuals with GS contains a decreased amount of bilirubin diglucuronides and an increased amount of bilirubin monoglucuronides compared to normals[48,51,256,277] (Fig. 4-9). This distribution is similar to that seen in infants.[278] Administration of phenobarbital has been shown to normalize the bile pigment profile in duodenal fluid,[51] lower plasma bilirubin levels, and increase hepatic clearance of bilirubin.[279,280] Clofibrate and glutethimide also normalize serum bilirubin concentrations but do not normalize the duodenal bile pigment profile.[281] In animals clofibrate is an inducer of BUGT but does not effect BSP uptake or GST.[282] An additional unexplained phenomenon in GS is the exaggerated rise in serum bilirubin associated with fasting.[283-286] Although normal individuals can double their serum bilirubin level in response to fasting, in GS a more pronounced rise occurs. This is not related to decreased hepatic blood flow because ICG clearance is not affected.[284] Although fasting can reduce BUGT activity[286] and increase HO (the enzyme responsible for bilirubin production) activity,[287] neither of these effects are believed to explain the fasting hyperbilirubinemia of GS.[279,288] Enhanced enterohepatic circulation of bilirubin is suggested to be a major factor in the pathogenesis of fasting-induced hyperbilirubinemia.[289] Intraluminal noncalorie food-bulk can blunt the bilirubin rise.[290]

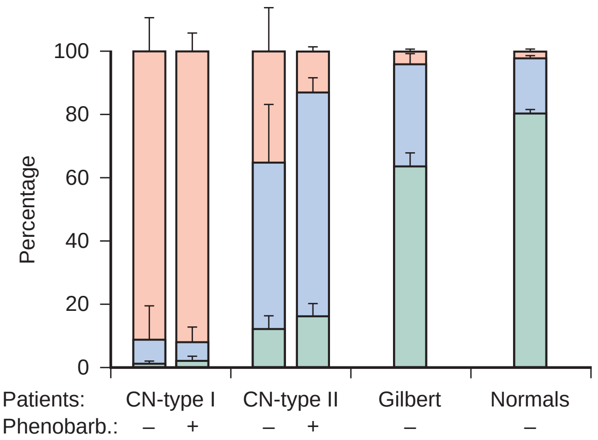

Figure 4-9 Bile pigment composition in bile from normal (n = 8), Crigler-Najjar (CN) type I (n = 3), CN type II (n = 3), and Gilbert's syndrome (n = 16) patients, receiving (+) or not receiving (-) phenobarbital. Relative bile pigment composition is indicated in the vertical columns as percentage of total ± SD. *Blue,* Bilirubin monoconjugate; *green,* bilirubin diconjugate; *red,* unconjugated bilirubin. *(From Sinaasappel M, Jansen PL: The differential diagnosis of Crigler-Najjar disease, types 1 and 2, by bile pigment analysis.* Gastroenterology *100:783–9, 1991.)*

Diagnosis and Treatment. Generally, a diagnosis of GS can be made when there is a mild, fluctuating unconjugated hyperbilirubinemia, the rest of the liver function tests are normal, and there is no hemolysis. Hemolysis can add confusion because it can result in similar findings and it is not unusual in GS. Hence other tests are sometimes used to aid in diagnosis, including the intravenous administration of nicotinic acid (niacin)[291] or one oral dose or rifampin[292] with assessment of the subsequent rise in serum bilirubin concentration.

Another test suggested to aid in the diagnosis of GS involves fractionation of the total serum bilirubin using alkaline methanolysis and thin-layer chromatography.[73,185] This allows precise measurement of the conjugated and UBIL levels. This approach has shown that in GS ~6% of the total serum bilirubin was conjugated compared to approximately 17% in normals and those with chronic hemolysis. Individuals with chronic persistent hepatitis had 28% of their total bilirubin present as conjugates. Fasting did not change the percentage of conjugates in GS, despite the rise in total serum bilirubin concentration. An overlap of only three individuals was seen among the 77 with GS and 60 normal subjects.[185] Other studies support these findings.[293] In patients with GS, fractionation of the total serum bilirubin by HPLC showed significantly decreased bilirubin monoglucuronides (1.1% vs. 6.2% in normals) and increased UBIL (98.8 vs. 92.6 in normals).[294]

Currently genetic testing is easily available to diagnose GS.[295] Monaghan et al.[243] have suggested GS genetic screening for the *UGT1A1* TA repeat as a simple, useful additional test in the investigation of very prolonged neonatal jaundice in North American, African, and

European populations; and for the Gly71Arg mutation in Asians. However, the value of such a genetic test cannot be fully determined until accurate data regarding the prevalence and penetrance of the GS genotype are known.[296] Thus genetic testing for GS cannot be routinely recommended.[296]

GS has no significant negative implications regarding morbidity or mortality. In general, drug metabolism studies have revealed no major dangers,[293,297] although there appears to be an increased incidence of slow acetylators,[298,299] and lorazepam clearance is 20% to 40% decreased.[300] Concurrent genetic deficiencies in other xenobiotic pathways may put individuals with GS at increased risk of drug toxicity to such compounds as acetaminophen,[301,302] cancer chemotherapeutic agents CPT-11 (irinotecan)[303] or TAS-103,[304] or the viral protease inhibitor, indinavir.[215,305] For this reason, Bosma suggests that screening for GS is of clinical importance.[215] No specific treatment is necessary for GS, though phenobarbital has been shown to lower serum bilirubin levels in these patients.[306] If the well-documented antioxidant effect of bilirubin[307] provides a biologic advantage,[308] then the mild hyperbilirubinemia of GS might actually be a significant benefit against such things as vascular disease,[309,310] in which free radicals are involved in pathogenesis. However, Bosma concludes that a selective advantage in GS because of the antioxidant capacity of bilirubin seems unlikely.[215]

Crigler-Najjar Syndrome Types I and II

In 1952, Crigler and Najjar described seven infants with congenital familial nonhemolytic jaundice who developed severe unconjugated hyperbilirubinemia shortly after birth and died from kernicterus within months.[311] These infants were from three related families. The serum bilirubin concentration reached 25 to 35 mg/dL despite a lack of hemolytic disease. Other liver function tests were normal. Liver histology was normal except for the deposition of bile pigments. Subsequent reports document that the main risk for patients with the CN is kernicterus.[1] An excellent review of the neurologic perspectives of CN has been published.[312] Although some patients survive into the second decade with normal development,[313] the possibility of developing late kernicterus is always a concern, even in adulthood.[314-317] Serum bilirubin levels vary from approximately 15 to 45 mg/dL.

In 1969, Arias and colleagues described a second, more frequent type of severe nonhemolytic hyperbilirubinemia.[318] The previous syndrome was termed CN type I (CNI, OMIM #218800), while the new findings were termed CN type II or Arias' syndrome (CNII, OMIM #606785).[318] Hyperbilirubinemia is less severe in type II patients and varies from approximately 8 to 25 mg/dL. Hence these individuals have a much lower incidence of kernicterus, though such damage occurs.[319,320]

Pathophysiology. Both CNI and CNII are generally inherited in an autosomal recessive manner, though one case of autosomal dominant inheritance of CNII has been reported.[321] CNI and CNII result from mutations to the *UGT* gene complex.[41] Patients with one normal allele demonstrate normal metabolism of bilirubin.[322] The genetic details determine the severity of clinical disease. In CNI there is a complete absence of functional UGT1A1, while in CNII, UGT1A1 activity is markedly reduced.[323] In CNI, 18 of 23 described mutations of the *UGT1* gene are found in the common exons 2 to 5 (see Fig. 4-4) and thus affect many UGT1 enzymes.[41,324] Intronic mutations causing CNI have also been reported.[325] However, in CNII four out of nine known mutations are found in exon 1A1. There is some overlap in classification of mild CNII and GS (e.g., Gly71Arg) which relate to differences in definitions based on serum bilirubin levels.[41] The TATA box TA_7 repeat mutation seen in GS can be seen along with other mutations resulting in either CNI or CNII.[326] In both CNI and CNII, assays of liver tissue from affected patients demonstrate negligible or very low BUGT activity.[48,49,256,315,318,327,328] Hence patients with these disorders experience a profound block in bilirubin excretion, because they lack the ability to conjugate bilirubin with UDPGA. Thus liver biopsy is not helpful in differentiating CNI and CNII. Study of the resected livers from four patients with CNI undergoing liver transplantation showed that there was heterogeneous glucuronidation of various substrates other than bilirubin.[329] Hence several in the family of glucuronosyltransferase isoenzymes can be affected in the same patient. There is considerable overlap of hepatic BUGT activity between CNII and GS[256] (see Table 4-2).

In family studies of CNI patients,[330,331] partial deficiencies have been found in the glucuronidation of salicylate and menthol among siblings, parents, and grandparents. Hence it has generally been accepted that this represents an autosomal recessive inheritance.[330] In family studies of CNII patients, the original report by Arias and colleagues found abnormalities of glucuronidation (menthol) in only one parent, suggesting autosomal dominant inheritance. Subsequent studies of siblings or parents often found elevated serum bilirubin levels (1.2 to 4 mg/dL), delayed bilirubin clearance tests, and decreased hepatic BUGT activity, as would be seen in GS.[280,315,318,320,332,333] These findings in both parents[280,332] suggested that CNII may represent homozygous GS. However, if CNII were truly the homozygous form of GS, one would expect many more affected individuals because GS occurs in at least 3% of the population. Pertinent genetic data have been reviewed[326] supporting the inheritance mode of CNII as autosomal recessive.

The major differentiating characteristic between CNI and CNII is the response to drugs that stimulate hyperplasia of the ER. When CNII patients received phenobarbital or diphenylhydantoin there was a significant decline in the serum bilirubin level, increased hepatic clearance of radiolabeled bilirubin,[280,318,319,334-337] and increased biliary levels of bilirubin diglucuronides[48,320] (see Fig. 4-9). In a study of five CNII patients, the magnitude of the phenobarbital induced decrease in serum bilirubin ranged from 2.1 to 12.1 mg/dL (27% to 72%) with pre- and postphenobarbital serum bilirubin levels ranging from 7.8 to 16.9 and 4.7 to 10.1 mg/dL, respectively.[48] Summarizing data from seven earlier studies[280,318,319,334-337] regarding the response of CNII patients to oral phenobarbital treatment revealed the following: 11 females and 13 males had a total serum bilirubin of 15.7 ± 13.8 (mean ± SD) prior to phenobarbital. After doses ranging from 90 to 390 mg/day, or alternatively 4 mg/kg/day, the serum bilirubin decreased 12 ± 4 mg/dL (77% ± 13%). The lowest total serum bilirubin following phenobarbital therapy was 5.9 mg/dL. In contrast, CNI patients show neither decrease in serum bilirubin nor significantly increased biliary bilirubin conjugates in response to drugs[48,314] (see Fig. 4-9). The response to phenobarbital is the criterion used to differentiate between these two disorders.[338] Bile analysis has also been suggested as another method to differentiate CNI and CNII.[48] In CNI, bile contains insignificant bilirubin conjugates (less than 10%), and UBIL predominates. In CNII, bile contains small amounts of bilirubin conjugates, and those present are predominantly bilirubin monoglucuronides (greater than 60%).[256]

Two cousins with CN have been described with unique features that raise the possibility of a new variant of this syndrome (type III).[339] This new variant resembled CNI in that there was no biliary excretion of bilirubin di- or monoglucuronide. However, the type III patients did excrete mono- and diglucoside conjugates of bilirubin. It has been speculated that type III patients lack the long proposed permease[39] that has been hypothesized to transport UDP-glucuronic acid to the luminal side of the ER, where glucuronosyltransferase is located. This absence is suggested to force utilization of a very inefficient substrate for conjugation to bilirubin, UDP-glucose.

Diagnosis and Treatment. Although CN can be diagnosed during the prenatal period,[340,341] evaluation of infants with CN more typically begins during the first days of life when serum bilirubin levels exceed 20 mg/dL. The conjugated fraction will not be elevated except possibly for the factitious elevation sometimes seen when the total serum bilirubin level is very high.[106] Evaluation of such infants will eliminate hemolysis, hypothyroidism, infection, and other more common causes of jaundice. Formula feedings will help identify those infants with jaundice related to human milk. During this period of testing, the magnitude of the serum bilirubin elevation will prompt use of phototherapy to avoid kernicterus.[126] Exchange transfusion may be necessary. Yet despite these efforts, CN patients will have persistent jaundice. There is currently no widely available simple clinical test to confirm a diagnosis of CN. CN can be excluded by finding significant amounts of bilirubin conjugates in neonatal stools, if collected prior to establishment of sufficient intestinal bacteria that convert bilirubin conjugates to urobilinoids.[1] High pressure liquid chromatographic (HPLC) analysis of duodenal bile will show that in CNI, there are negligible bilirubin di- or monoglucuronides, while in CNII these conjugates are present but in low concentration.[41,48] An easy method to collect such fluid for analysis utilizes the pediatric Entero-Test capsule.[277] This approach to diagnosis is much less invasive than performing a liver biopsy to confirm negligible BUGT activity with in vitro assay. The ratio of serum bilirubin conjugates (as determined by alkaline methanolysis with thin-layer chromatography) to total bilirubin, although abnormally low, does not allow differentiation of CN patients from those with GS.[185] Similar overlap occurs with HPLC fractionation of serum bilirubin conjugates.[294] DNA analysis can be very helpful in establishing the correct diagnosis,[342] and in the future it is expected that DNA array technology will allow rapid screening for known mutation.

A world registry of patients with CNI aimed at developing management guidelines has been published.[343] Phenobarbital (4 mg/kg/day in infants) should be used when there is concern about deficiency of BUGT. Within 48 hours CNII patients can demonstrate a significant decrease in serum bilirubin levels (as detailed above) and an increased biliary excretion of bilirubin di- and monoglucuronide,[49,320] while the CNI patients will show no significant response. Occasionally CNII patients do not respond to the first trial of phenobarbital therapy, but subsequent trials months later will demonstrate the significant decrease in serum bilirubin level.[338] However, despite the decrease in serum bilirubin in response to phenobarbital, CNII patients will usually continue to manifest a significant hyperbilirubinemia (approximately 5 to 15 mg/dL). Phototherapy for 6 to 12 hours daily has been the primary modality to keep serum bilirubin levels below 20 mg/dL during the first several months of life[344] because CNI patients can excrete all bilirubin photoisomers.[345] CNI patients will require lifelong treatment with phototherapy until more definitive therapy such as liver transplant. Phototherapy has been found to be least intrusive when given at night, and improvements have been made in effectiveness and comfort.[346,347] Although phototherapy is very helpful in infancy, in adolescence social inconvenience and compliance problems can bring increased risk of kernicterus.[343]

Other therapeutic considerations involve the oral administration of binding agents such as agar or cholestyramine or calcium phosphate.[348-351] These agents bind to bilirubin in the intestinal lumen due to phototherapy or through direct intestinal permeation.[352] They prevent the enterohepatic circulation of bilirubin. Problems associated with the use of cholestyramine include cost, taste, and concern about bile salt depletion and fat malabsorption. Problems regarding agar include significant variation in bilirubin binding affinity among various preparations and batches.[315,348,353] During acute episodes of severe hyperbilirubinemia after the first year of life, plasmapheresis has been shown to rapidly decrease serum bilirubin levels.[315,354] Peritoneal dialysis and exchange transfusion have not been helpful in this setting.[314] Repeated intramuscular injections of tin protoporphyrin, an HO inhibitor that blocks bilirubin formation, have been used in one CNI patient with data suggesting a decreased need for phototherapy.[355] Two patients with CNI were treated with tin mesoporphyrin to block bilirubin formation and also received daily phototherapy and intermittent plasmapheresis over a 400-day period.[356] They developed an iron deficiency anemia believed to be due to the porphyrin therapy,[357] but tin mesoporphyrin (stannsoporfin) (2 to 4 μmol/kg)[358] is suggested to offer a promising, though still experimental, additional therapy for controlling episodes of acute, severe jaundice.[359] Drugs which bind to albumin and can potentially displace bilirubin should be avoided at all times.[360]

Because patients with CN syndrome have good hepatic function other than conjugating bilirubin, they are ideal candidates for auxiliary liver transplantation, wherein the patient's own liver remains within the body while another whole or partial liver is transplanted just beneath or adjacent to the recipient's. This option has recently become clinically available.[361-363] More commonly, orthotopic liver transplantation has been performed,[364-371] and this represents the only true cure for the hyperbilirubinemia of CNI. Ideally the timing of transplantation would precede irreversible neurologic injury.[372,373] Transplantation of other BUGT-containing tissues (e.g., segments of small intestine,[374,375] kidneys,[376] or hepatocytes[377]) remain experimental. Successful cloning of the gene responsible for bilirubin glucuronosyltransferase activity offers the hope of future gene therapy to correct this deficiency based on studies in Gunn rats, the congenitally jaundiced model for CNI.[372,378-380]

Disorders of Enterohepatic Circulation

Increased enterohepatic circulation of bilirubin is believed to be an important factor in neonatal jaundice. As previously reviewed, neonates are at risk for the intestinal absorption of bilirubin because (1) their bile contains increased levels of bilirubin monoglucuronide, which allows easier conversion to bilirubin; (2) they have significant amounts of β-glucuronidase within the intestinal lumen, which hydrolyses bilirubin conjugates to bilirubin, which is more easily absorbed from the intestine; (3) they lack an intestinal flora to convert bilirubin conjugates to urobilinoids; and (4) meconium, the intestinal contents accumulated during gestation, contains significant amounts of bilirubin.[381] Conditions that prolong meconium passage (e.g., Hirschsprung's disease, meconium ileus, meconium plug syndrome) are associated with hyperbilirubinemia.[382,383] Earlier passage of meconium has been shown to be associated with lower serum bilirubin levels.[384,385] This may be facilitated by rectal temperature measurement during the neonatal period.[386] The enterohepatic circulation of bilirubin can be blocked by the enteral administration of compounds which bind bilirubin, such as agar,[85,348,353,387] charcoal,[388] and cholestyramine.[349]

Other Causes of Unconjugated Hyperbilirubinemia

Various hormones may cause development of neonatal unconjugated hyperbilirubinemia. Congenital hypothyroidism can present with serum bilirubin greater than 12 mg/dL prior to the development of other clinical findings.[389] Prolonged jaundice is seen in one third of infants with congenital hypothyroidism.[390] Similarly hypopituitarism and anencephaly may be associated with jaundice due to inadequate thyroxine, which is necessary for hepatic clearance of bilirubin.

Certain drugs may affect the metabolism of bilirubin and result in hyperbilirubinemia or displacement of bilirubin from albumin. Such displacement increases the risk of kernicterus and can be caused by sulfonamides,[391] moxalactam,[392] and ceftriaxone[393] (independent of its sludge-producing effect[394]). The popular Chinese herb, Chuen-Lin, given to 28% to 51% of Chinese newborn infants, has been shown to have a significant effect in displacing bilirubin from albumin.[395] Pancuronium bromide[164] and chloral hydrate[396] have been suggested as causes of neonatal hyperbilirubinemia.

Infants of diabetic mothers have higher peak bilirubin levels and a greater frequency of hyperbilirubinemia compared with normal neonates.[397] These patients have shown a positive correlation between total bilirubin and hematocrit, thus implicating polycythemia as one possible mechanism.[397] Other potential reasons for this hyperbilirubinemia include prematurity, substrate deficiency for glucuronidation (secondary to hypoglycemia), and poor hepatic perfusion (secondary to either respiratory distress, persistent fetal circulation, or cardiomyopathy).

The Lucey-Driscoll syndrome[398] consists of neonatal hyperbilirubinemia within families in whom there is in vitro inhibition of glucuronosyltransferase by both maternal and infant serum. It is presumed that this is caused by gestational hormones.

Prematurity is frequently associated with unconjugated hyperbilirubinemia in the neonatal period. Hepatic UDP-glucuronosyltransferase activity is markedly decreased in premature infants and rises steadily from 30 weeks' gestation until reaching adult levels 14 weeks after birth.[399] In addition there may be deficiencies for both uptake[400] and secretion.[401] Bilirubin clearance improves rapidly following birth.[402]

Hepatic hypoperfusion can result in neonatal jaundice. Inadequate perfusion of the hepatic sinusoids may not allow sufficient hepatocyte uptake and metabolism of bilirubin. Causes might include patent ductus venosus,[403] congestive heart failure, and portal vein thrombosis. Other specific liver diseases, as listed in Box 4-1 and described elsewhere in this text, can result in neonatal jaundice.

MANAGEMENT AND TREATMENT OF UNCONJUGATED HYPERBILIRUBINEMIA

In recent years changes in perinatal care have made severe neonatal jaundice a larger problem and there has been a reemergence of kernicterus.[404-406] Possible reasons for this include[406,407] (1) early hospital discharge (before extent of jaundice is known and signs of impending brain damage have appeared);[408] (2) lack of adequate concern for the risks of severe jaundice in healthy term and near newborns;[405] (3) an increase in breastfeeding incidence;[169] (4) medical care cost constraints; (5) paucity of educational materials to enable parents to participate in safeguarding their newborns; (6) limitations within in health care systems to monitor the outpatient progression of jaundice;[409] (7) difficulty in estimating the degree of jaundice, particularly in dark-skinned infants;[410] and (8) demonstration of bilirubin being an antioxidant.[20] Newborn infants are now being described who are

Box 4-1 **Causes of Neonatal Hyperbilirubinemia**

INCREASED PRODUCTION OF BILIRUBIN

- Fetal–maternal blood group incompatibilities
    - Extravascular blood in body tissues
    - Polycythemia
    - Red blood cell abnormalities (hemoglobinopathies, membrane, and enzyme defects)
    - Induction of labor

DECREASED EXCRETION OF BILIRUBIN

- Increased enterohepatic circulation of bilirubin
    - Breastfeeding
    - Inborn errors of metabolism
    - Hormones and drugs
    - Prematurity
    - Hepatic hypoperfusion
    - Cholestatic syndromes
    - Obstruction of the biliary tree

COMBINED INCREASED PRODUCTION AND DECREASED EXCRETION OF BILIRUBIN

- Sepsis
    - Intrauterine infection
    - Congenital cirrhosis

From Suchy FJ, Sokol RJ, Balistreri WF, editors: Liver disease in children, *ed 3, New York, 2007, Cambridge University Press.*

discharged early, develop severe hyperbilirubinemia (30 to 40 mg/dL) at home, and go on to develop classic signs of kernicterus.[1,121,405,411-414] This has been reported in otherwise healthy breastfed infants with no other identified etiology for their jaundice.[415-417] Although early postpartum discharge has advantages, one disadvantage is the risk associated with delayed diagnosis of severe hyperbilirubinemia. The AAP has recommended that infants discharged at less than 48 hours of age be seen in follow-up within 48 hours of discharge.[418] Many physicians do not follow these recommendations,[121,419] despite the serious impact that short hospital stay has on the jaundiced newborn.[420] The AAP updated their 1994 guidelines[421] for the management of hyperbilirubinemia in newborn infants in 2004.[121]

Jaundice can be caused by increased bilirubin production, decreased bilirubin excretion, or combinations of these mechanisms (see Box 1 for specific examples). An approach to management of jaundice in the newborn nursery has been published elsewhere.[121] Although Newman and colleagues found that obtaining a direct bilirubin measurement was seldom helpful because of low yield and poor specificity,[422] others advocate measurement of an early conjugated bilirubin as a population screening test, which could lead to the earlier diagnosis of neonatal liver disease.[423] Bhutani and colleagues advocated universal bilirubin measurement prior to hospital discharge in order to identify infants at risk for severe neonatal hyperbilirubinemia on the basis of a predischarge hour specific total serum bilirubin measurement[424,425] (Fig. 4-10). Such universal predischarge screening is now recommended by the AAP[121] and has been shown in one recent study to reduce the incidence of significant hyperbilirubinemia and the rate of hospital readmission of infants for the treatment of jaundice.[426] Despite the large number of etiologies for neonatal jaundice, no cause for the jaundice could be identified in nearly half of the infants evaluated during one study of 447 infants[97] and in one third of the infants in a kernicterus registry.[417]

Hyperbilirubinemia is the most frequent reason that infants are readmitted to the hospital in the first weeks of life.[408,427,428] The management of neonatal jaundice has been reviewed elsewhere[121] (Figs. 4-11 and 4-12). The most important step in treatment of jaundice is determination of the primary etiology. However, independent of the etiology of the jaundice, elevation of the serum UBIL fraction prompts concern about possible kernicterus. As previously reviewed,[132,141] when the UBIL fraction is elevated, care must be given to avoid administration of agents which bind to albumin and displace bilirubin, thus promoting kernicterus. Although

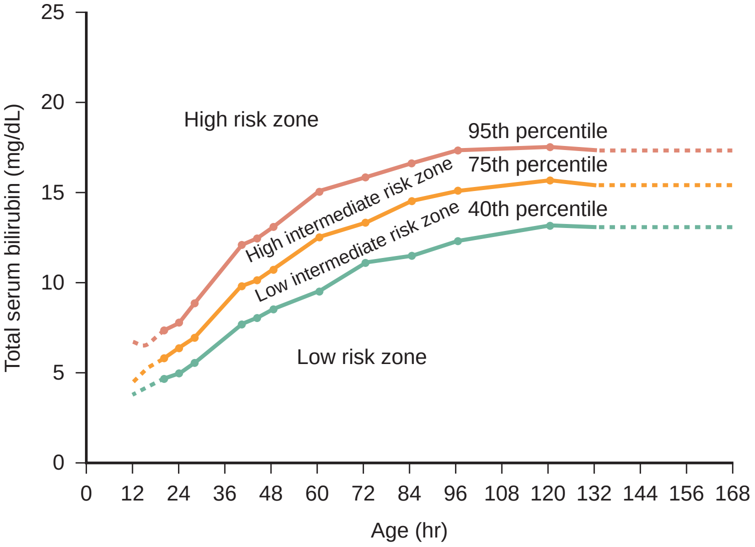

Figure 4-10 Risk designation of term and near term–well newborns based on their hour-specific serum bilirubin values. *(From Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns.* Pediatrics *103:6–14, 1999. American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation.* Pediatrics *114:297–316, 2004.)*

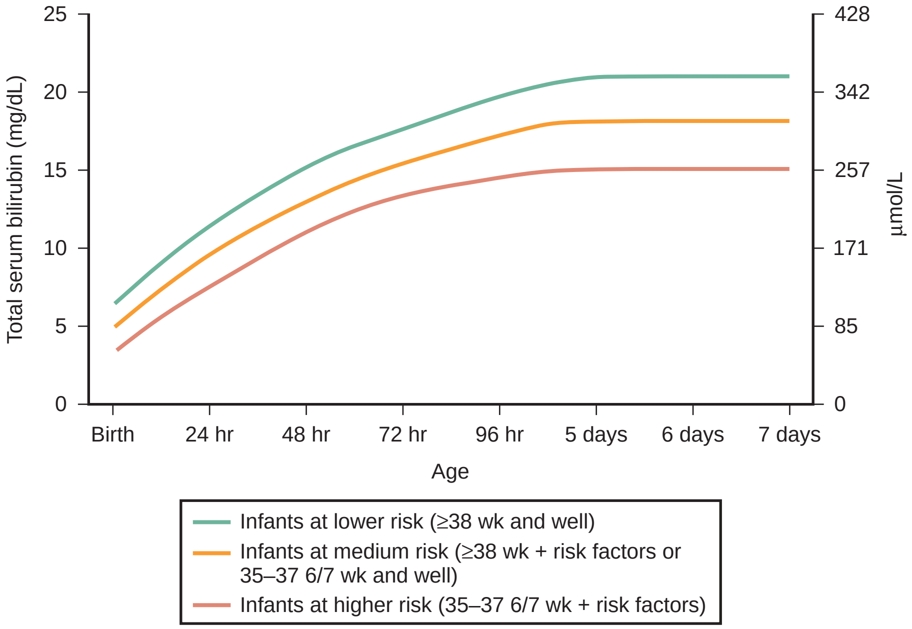

Figure 4-11 Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation. These guidelines are based on limited evidence, and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy, which should be used when the TSB exceeds the line indicated for each category. *Intensive phototherapy* implies irradiance in the blue-green spectrum (wavelengths of approximately 430 to 490 nm) of at least 30 µW/cm^2 per nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's surface area as possible. If the total serum bilirubin does not decrease or continues to rise in an infant who is receiving intensive phototherapy, this strongly suggests the presence of hemolysis. Infants who receive phototherapy and have an elevated direct-reacting or conjugated bilirubin level (cholestatic jaundice) may develop the bronze-baby syndrome. Use total bilirubin; do not subtract direct reacting or conjugated bilirubin. Risk factors: isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis or albumin less than 3 g/dL. For well infants 35 to 37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wks and at higher TSB levels for those closer to 37 6/7 wk. It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2 to 3 mg/dL (35 to 50 µmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors. *(From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation.* Pediatrics *114:297–316, 2004.)*

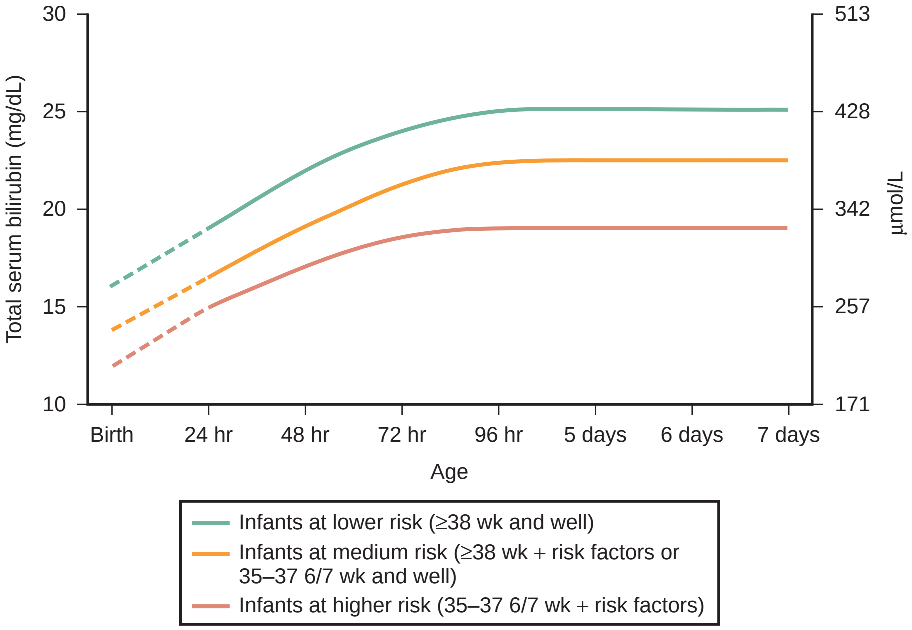

Figure 4-12 Guidelines for exchange transfusion in infants 35 or more weeks' gestation. These suggested levels are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if the TSB rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, repeat TSB measurement every 2 to 3 hours and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours. The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy. Immediate exchange transfusion is recommended if an infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if TSB is greater than or equal to 5 mg/dL (85 µmol/L) above these lines. Risk factors: isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis. Use total bilirubin; do not subtract direct reacting of conjugated bilirubin. If infant is well and 35 to 37 6/7 wk (median risk), one can individualize TSB levels for exchange based on actual gestational age. *(From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation.* Pediatrics *114:297–316, 2004.)*

historically, sulphonamides are the most well known bilirubin displacing agents, drugs such as ceftriaxone and ibuprofen are also strong bilirubin displacers with a potential for inducing bilirubin encephalopathy.[393,429] Therapeutic options to lower UBIL levels include phototherapy, exchange transfusion, interruption of the enterohepatic circulation, enzyme induction, and alteration of breastfeeding. Research into these and other modalities continues actively. The outcome of rational therapeutic guidelines for unconjugated hyperbilirubinemia during the first 7 days of life have been published elsewhere;[430] phototherapy can reduce the incidence of exchange transfusion and the risk of bilirubin-induced neurologic disease.

Phototherapy

Phototherapy consists of irradiation of the jaundiced infant with light.[431,432] Photon energy derived from light changes the structure of the bilirubin molecule in two ways (Fig. 4-13), allowing bilirubin to be excreted into bile or urine without the usual requirement for hepatic glucuronidation. One change involves a 180-degree rotation around the double bonds between either the A and B or C and D rings,[433] converting the normal Z configuration to the E configuration. 4Z,15E bilirubin is preferentially formed and can spontaneously reisomerize to native bilirubin. More importantly a new seven-membered ring structure can be formed between rings A and B, resulting in *lumirubin*[434] or *cyclobilirubin*[435] via the 4E,15Z-isomer intermediate.[436] The isomerization interferes with the internal hydrogen bonding of native bilirubin and by exposing the propionic acid groups result in a more polar compound. Thus the lumirubin and E isomers can be excreted directly into bile. Lumirubin appears to be the major route by which bilirubin is eliminated with phototherapy.[437,438] The choice of light for phototherapy is a subject about which there is much conflicting data.[431] Special blue light (or Super Blue, but not regular blue) appears to be better than white or green light, though white is less disturbing to nursery personnel.[439] Phototherapy devices utilizing woven fiberoptic pads are currently available,[440] effective (comparable to conventional phototherapy), safe, eliminate the need for eye patches, and permit greater time for maternal–infant bonding.[441-443]

Proposed guidelines for phototherapy have been published elsewhere.[121] In general, phototherapy is used to prevent serum bilirubin concentrations from reaching levels necessitating exchange transfusion (see Fig. 4-11). Phototherapy is now frequently done at home,[444,445] a practice accepted and recommended by the AAP.[121] Despite documented complications, such as skin rash, loose bowel movements, overheating, and dehydration,[446-448] phototherapy is widely used and generally safe.[449] Although phototherapy does effect cardiac output, blood flow to other organs (e.g., increased cerebral blood flow), and may be associated with opening of the ductus arteriosus, these effects are generally not problematic.[450,451] In extremely premature infants (less than 800 g birthweight) prolonged phototherapy and low peak serum bilirubin levels (less than 9.4 mg/dL) were shown in one study to be independently associated with blindness.[452] This could possibly be related to direct effects of light on the unshielded immature eye or decreased antioxidant protection by low serum bilirubin levels. Phototherapy should not be employed without prior diagnostic evaluation of the cause of the jaundice. The shielding of phototherapy units should never be removed because of the ultraviolet radiation hazards that can result.[453] Although it has been recommended that the infants position be changed every 6 hours during phototherapy,[454] data from one study showed position change made no difference in serum bilirubin levels.[455] One study of 264 neonates (some with hemolytic jaundice) who completed an average of 121 hours of phototherapy indicated that significant rebound hyperbilirubinemia did not occur.[456] Similarly no significant rebound hyperbilirubinemia occurred in 163 healthy, full-term infants with nonhemolytic jaundice (including breast-, formula- and mixed-feedings) receiving an average of 54 to 65 hours.[457] In full-term, healthy newborns, phototherapy may be stopped when the serum bilirubin level falls below 14 to 15 mg/dL, and hospital discharge need not be delayed to observe for rebound.[421]

Exchange Transfusion

Exchange transfusion is the most rapid method to acutely lower the serum bilirubin concentration. Indications for exchange transfusion vary, have been published elsewhere,[121,446,458-460] and are detailed in Chapter 2. They can be related to either anemia or elevated serum bilirubin level. The AAP has published guidelines which represent the most widely accepted indications for initiation of exchange transfusion based on risk factors, including hour-specific total bilirubin level; response to intensive phototherapy; serum bilirubin-to-albumin ratio; and the presence of hemolytic disease, sepsis, acidosis, or other acute conditions (see Fig. 4-12). Additionally exchange transfusion should be initiated if the infant displays signs of acute bilirubin encephalopathy (see section on bilirubin encephalopathy). In neonatal hemolytic disease, suggested indications for transfusion include (1) anemia (hematocrit less than 45%), positive direct Coombs test, and bilirubin greater than 4 mg/dL in the cord blood; (2) postnatal rise of the serum bilirubin concentration that exceeds 1 mg/dL/hr for more than 6 hours; (3) progressive anemia and rate of increase in serum bilirubin of greater than 0.5 mg/dL/hr; and (4) continuing progression of anemia despite control of hyperbilirubinemia. Sometimes exchange transfusion for hemolytic disease can be avoided through the use of high-dose intravenous immunoglobulin therapy.[461] Suggested indications for exchange transfusion because of hyperbilirubinemia alone include (1) bilirubin concentration greater than 15 mg/dL for more than 48 hours; (2) salicylate saturation index greater than 8 or HABA binding less than 50% on two successive determinations 4 hours apart; (3) ratio of total serum bilirubin (mg/dL) divided by total serum protein (g/dL) greater than 3.7; and (4) molar concentration ratio of serum bilirubin to serum albumin of greater than 0.7.[446] Although there are many well described risks with exchange transfusion, mortality should be low (less than 0.6%) if it is performed properly.[402,462,463]

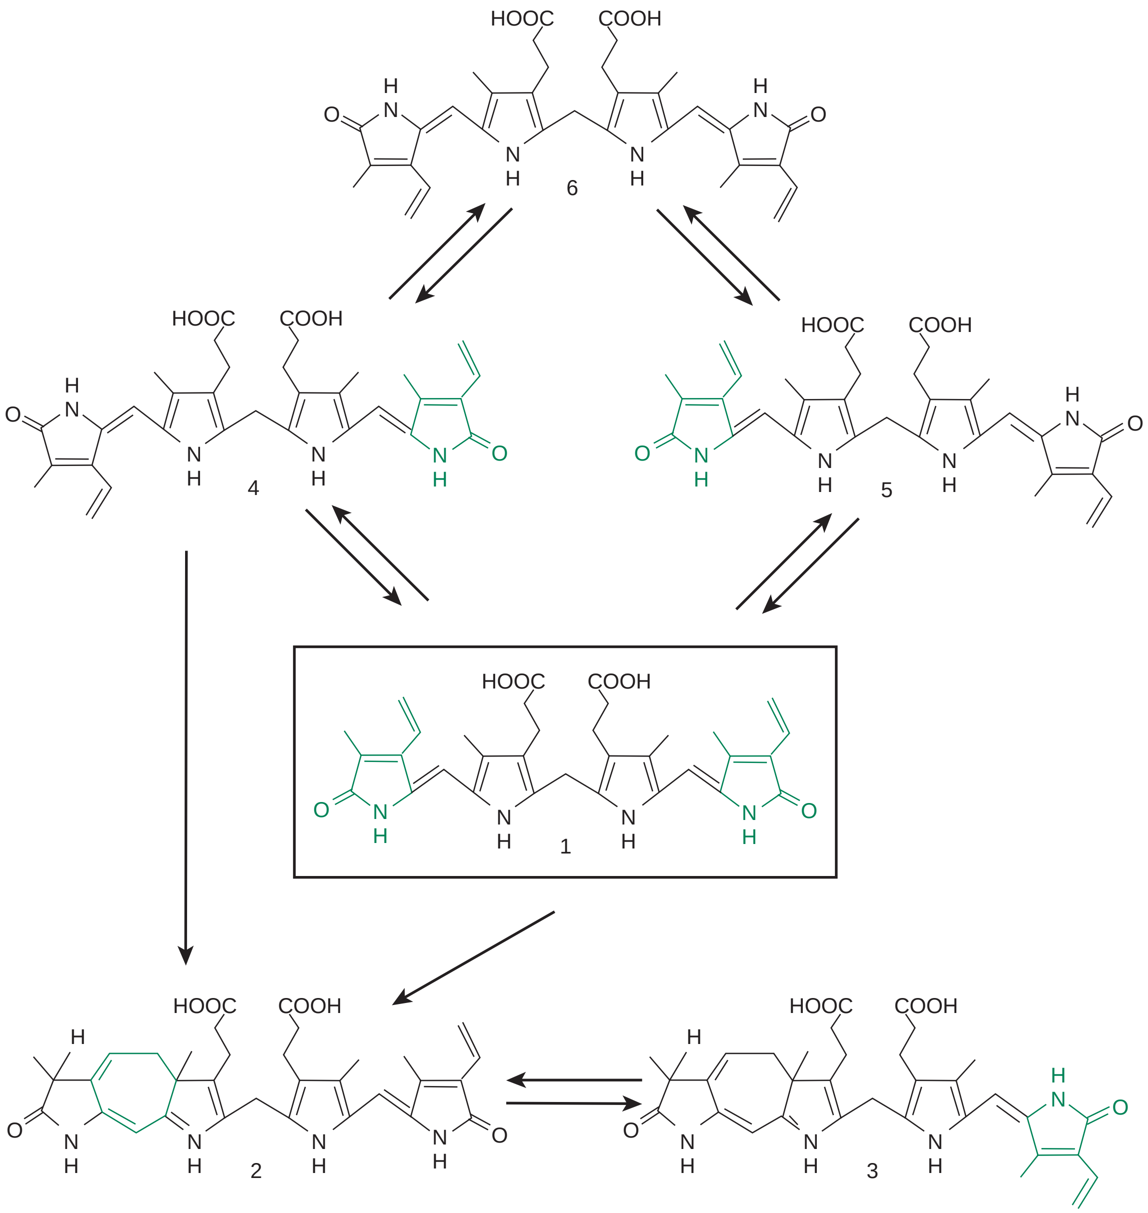

Figure 4-13 The products of phototherapy. Light induces an isomerization of 4*Z*,15*Z*-bilirubin (1) to produce the configurational isomers 4*E*,15*Z*-bilirubin (4), 4*Z*,15*E*-bilirubin (5), 4*E*,15*E*-bilirubin (6) and the structural isomers, *Z*-lumirubin (2) and *E*-Lumirubin (3) as shown. Isomerization exposes one or both of the propionic acid side chains, increasing the polarities of the isomers with respect to biosynthetic bilirubin (1) and allowing excretion in bile without hepatic glucuronidation. Formation of 4*E*,15*Z*-bilirubin, 4*Z*,15*E*-bilirubin, 4*E*,15*E*-bilirubin is reversible, and these isomers spontaneously revert to the parent 4*Z*,15*Z*-bilirubin (1) isomer after excretion in bile. The predominant isomer present in the circulation of infants exposed to light or phototherapy is 4*Z*,15*E*-bilirubin (5). Although the structural isomers (2 and 3) are formed more slowly than the configurational isomers, they may contribute more to the overall effect of the treatment because of their relatively faster excretion. *(From Antony McDonagh: Phototherapy: From ancient Egypt to the new millenium.* J Pernatol *21:S7–12, 2001.)*

Pharmacotherapy

There are a number of pharmacologic approaches to the prevention and treatment of neonatal hyperbilirubinemia that have been recently reviewed.[464] The enterohepatic circulation can be interrupted by enteral administration of agents that bind bilirubin in the intestine and prevent reabsorption. Such agents include agar,[85,348,353] cholestyramine,[349] activated charcoal,[388] and calcium phosphate.[351,465,466] Increased intestinal peristalsis would be expected to allow less time for bilirubin absorption. Frequent feedings[467] and rectal stimulation[386] are associated with lower serum bilirubin levels. Enteral feedings of bilirubin oxidase, an enzyme that degrades bilirubin to biliverdin, dipyrrols, and other unidentified products,[468] are an additional method to block the enterohepatic circulation that remain experimental at present.[469] Another experimental approach utilizes intravenous bilirubin oxidase.[470,471]

Because neonatal hepatic BUGT activity has been shown to be low in neonates,[399] it is not surprising that induction of hepatic BUGT results in lower serum bilirubin levels. Such induction in the neonate can be accomplished with prenatal maternal use of phenobarbital or diphenylhydantoin.[472,473] Even very low birth weight infants (less than 2000 g) have been shown to respond to in utero phenobarbital therapy, with significantly increased serum levels of conjugated bilirubin and decreased need for phototherapy.[474] In the postnatal period, use of phenobarbital by the neonate has the same bilirubin-lowering effect.[475] Clofibrate is advocated by French workers as a simple, nontoxic pharmacologic treatment which induces BUGT and is used increasingly in France to prevent and treat neonatal jaundice.[476] An alternative approach to treat neonatal hyperbilirubinemia is to block the first enzyme responsible for the production of bilirubin, HO. This can be accomplished by several different metalloporphyrins.[477,478] Sn-protoporphyrin has been used successfully in the experimental management of jaundice in neonates with ABO incompatibility.[479] Treatment of neonatal jaundice with HO inhibition remains experimental at this point in time, though clinical trials appear promising. Two studies with Sn-mesoporphyrin (Sn-MP) showed that phototherapy could be abolished by using Sn-MP.[480,481] In addition to inhibiting bilirubin production, metalloporphyrins are photosensitizers, which can accelerate the destruction of bilirubin by light but also cause other unwanted side effects.[482] Because CO is now suggested to be a significant neurotransmitter,[483] blocking HO activity early in life may not be a completely benign process. Thus a major concern about metalloporphyrins is the lack of detailed long term follow-up studies addressing safety issues.[484] At the present time, phototherapy and exchange transfusion remain the primary modes to control neonatal unconjugated hyperbilirubinemia, and pharmacologic interventions remain largely adjunctive or experimental.

Feeding Strategies

Optimization of breastfeeding in the perinatal period is important.[485] If the bilirubin level is rising, published recommendations support encouraging mothers to breastfeed more frequently,[421,486,487] with an average suggested interval between feeds of 2 hours and no feeding supplements[488] or at least 8 to 10 feedings per 24 hours.[421] A strong dose-response relationship has been shown between feeding frequency and a decreased incidence of hyperbilirubinemia.[489] More frequent nursing may not increase intake, but it has been suggested to increase peristalsis and stool frequency, thus promoting bilirubin excretion.[458] Frequency of breastfeeding during the first 24 hours of life has been shown to be correlated significantly with the frequency of meconium passage.[489] The serum bilirubin level at which breastfeeding should be discontinued is controversial, and recommendations include 14,[490] 15,[175] 16 to 17,[487] and 18 to 20 mg/dL.[488] When breastfeeding is interrupted, formula feeding may be initiated for 24 to 48 hours, or breastfeeding and formula-feeding can be alternated with each feeding.[421] No studies have addressed the cost effectiveness of various formulas in their jaundice-lowering effects, though two independent studies have shown that infants exclusively fed Nutramigen™ (a casein hydrolysate formula, Mead Johnson) have lower jaundice levels than infants fed routine formula.[491,492] Supplementing breastfed infants with small volumes of specific nutritional ingredients has been shown to result in increased fecal bilirubin excretion and lower TcB levels,[96] though no commercial preparations of these ingredients are currently available. Feeding heated, expressed breastmilk is also said to reduce serum bilirubin levels.[488] A fall in the serum bilirubin level of 2 to 5 mg/dL[458] is consistent with a diagnosis of breastmilk jaundice. Breastfeeding may then be resumed with the acknowledgment that serum bilirubin levels may rise for several days but will gradually level off and decline.[175,486] If breastfeeding is to be resumed following the interruption, it is important to preserve lactation with the use of a breast pump. In one study, interruption of breastfeeding for approximately 50 hours (during which time a formula was given) was shown to have the same bilirubin-lowering effect as a similar duration of phototherapy.[493] Interruptions of breastfeeding for 24 to 48 hours have been shown to be successful at lowering serum bilirubin levels and avoiding the need for phototherapy in 81 of 87 jaundiced infants.[490] Formula feedings to Asian neonates receiving phototherapy resulted in greater decrease of serum bilirubin levels than infants who were exclusively breastfed.[457] Careful counseling and support can prevent the interruption of breastfeeding from becoming a permanent discontinuance of nursing.[490]

DISORDERS OF CONJUGATED HYPERBILIRUBINEMIA

Rotor Syndrome

Rotor syndrome, (RS) (OMIM #237450) first described in 1948, is a familial disorder which involves chronic elevation of both the conjugated and unconjugated serum bilirubin fractions.[494,495] Half or more of the total serum bilirubin is conjugated, and total bilirubin levels usually range from 2 to 7 mg/dL but occasionally may reach 20 mg/dL.[496] Liver functions tests are otherwise normal, and there is no evidence of hemolysis. Liver histology is normal when examined with both light and electron microscopy. Oral cholecystograms reveal normal gallbladder opacification. This disorder can present in early childhood[497] or possibly the first months of life, if coinherited with G6PD deficiency or heterozygous β-thalassemia,[498] and manifests no gender predisposition. Family studies suggest an autosomal recessive mode of inheritance.[494,495,499]

Pathophysiology

OMIM now indicates that the primary abnormality in RS is simultaneous mutation in the SLCO1B1 and SLCO1B3 genes, which are neighboring genes, leading to nonfunctional organic anion transporter peptides OATP1B1 and OATP1B3. Recent data in eight RS families found these mutations and suggest that interference with the hepatic uptake of bilirubin glucuronide by the nonfunctional OATP1B1/1B3 transporters results in elevated conjugated and unconjugated serum bilirubin levels.[500] Previously there was thought to be a deficiency in the intracellular storage capacity of the liver for binding anions,[501,502] which can be demonstrated by constant infusions of BSP and ICG.[503] Patients with RS demonstrate a delayed plasma clearance of both BSP and ICG, and heterozygotes show delayed BSP clearance with values intermediate between normals and those with homozygous RS.[501] GST serves as an intracellular carrier protein for certain organic molecules, acting as an intracellular equivalent to albumin in blood plasma.[504] A patient with RS has been shown to have a deficiency of hepatic GST,[505] and this would be consistent with observations regarding the pathogenesis of this disorder. Deficiency of GST would result in impaired uptake of bilirubin within the cytosol. In addition, because bilirubin conjugates are bound to GST while awaiting excretion from the hepatocyte via the canalicular membrane,[506] deficient intracellular storage would result in leakage of bilirubin conjugates back into the circulation. Serum elevations of both conjugated and nonconjugated bilirubin result.

Another important observation in RS relates to the urinary excretion of coproporphyrin. In normal, healthy individuals only the I and III isomers of coproporphyrin are excreted in the urine. In RS there is a marked increase in urinary coproporphyrin excretion, and, usually, less than 80% of the total (I + III) is isomer I (normal is 25%). Heterozygotes demonstrate urinary coproporphyrin values that are intermediate between normals and homozygotes.[507] Urinary excretion of coproporphyrin is believed to be increased because biliary excretion is impaired, similar to findings in other liver diseases.[508]

Diagnosis and Treatment

A diagnosis of RS should be considered in all individuals having elevation of both conjugated and nonconjugated serum bilirubin fractions along with otherwise normal liver function tests. The diagnosis can be confirmed by measuring urinary coproporphyrin levels, which are 2.5 to 5 times higher than normal levels.[507] Of the total urinary coproporphyrin isomers I plus III, isomer I constitutes less than 80% of the total in RS.[509] ^{99m}Tc-HIDA cholescintigraphy has also been shown to be useful to diagnose RS and demonstrates poor to no visualization of the liver.[510,511] Patients with RS require no specific therapy and are asymptomatic. Although jaundice is a lifelong finding, it is associated with no morbidity or mortality unless the cosmetics are a concern.

Dubin-Johnson Syndrome

Dubin-Johnson syndrome (DJS) (OMIM #237500), first described in 1954,[512] involves elevation of both the conjugated and unconjugated serum bilirubin fractions.[513] More than half of the total serum bilirubin is conjugated, and total bilirubin levels usually range from 1.5 to 6 mg/dL, though values have been reported as high as 25 mg/dL during intercurrent illness.[514] It is not unusual for patients with DJS to report vague abdominal complaints, though this is not believed to reflect serious pathology. Although hepatomegaly is sometime seen, liver functions tests are otherwise normal, including bile acids,[515] and there is no evidence of hemolysis.[512,513,516] Although this syndrome occurs in both sexes, males predominate and present at an earlier age. It occurs in all races; however, Iranian Jews have an increased incidence.[517,518] It is usually diagnosed after puberty, though cases have also been reported in neonates,[519] at which time cholestasis can be significant.[520-524] DJS is inherited as an autosomal recessive trait with heterozygotes manifesting normal serum bilirubin levels.[517,525,526] This syndrome is far more common than RS, and jaundice can be worsened by pregnancy and oral contraceptives.[527] Often the gallbladder is not visualized when patients with DJS undergo an oral cholecystogram.[513]

A striking characteristic of DJS is the brown to black discoloration of the liver. There is still debate about the identity of this pigment, which is located in the lysosomes.[528] Although originally thought to be lipofuscin, more recent data provide conflicting evidence for a relationship to melanin[529-531] or polymerized epinephrine or other metabolites[532,533] that accumulate in the lysosomes. It is hypothesized that these pigments accumulate in the liver because of impaired secretion of various metabolites from the hepatocyte into the bile.[533] This pigment disappears from the liver during acute viral hepatitis, with subsequent reappearance.[534] Other than this striking pigmentation, the liver is histologically normal. Recently, a black liver was reported in an individual who did not have DJS.[535]

Pathophysiology

The primary defect in the DJS is deficient hepatic excretion of non–bile-salt organic anions at the apical canalicular membrane, by the ATP-binding cassette (ABC) transport system known variously as cMOAT, MRP2, or ABCC2 (OMIM 601107).[536,537] cMOAT is encoded by a single copy gene located on chromosome 10q24.[538] Mutations of this gene have been shown to produce a highly defective cMOAT that is associated with DJS.[58,536,537,539-542] Similar findings made in the homologous cMOAT gene of two rat models of hyperbilirubinemia (TR[-] and Eisai) have been very helpful in understanding DJS in humans.[58]

Although hepatic BSP clearance tests are no longer performed, they nicely demonstrate the effect of deficient transport via the canalicular membrane, characteristic of DJS.[543] Initially the clearance rate of intravenously administered BSP from the circulation is rapid and results in a BSP retention that is often normal at 45 minutes. However, a subsequent rise in serum BSP concentration occurs at 90 and 120 minutes, because the conjugated BSP cannot be excreted and thus refluxes out of the hepatocyte back into the circulation.[543-546] Data suggest that BSP hepatic storage is normal, but there is a 90% decrease in the BSP excretory transport maximum.[527,545] Other substances (e.g., ICG, rose bengal, and dibromosulfophthalein) have also been shown to have a decreased excretory transport maximum, though these substances do not require hepatic biotransformation and do not show the late rise in plasma levels during clearance tests.[547] Hence in DJS, deficient excretion of bilirubin glucuronides at the canalicular membrane, in the presence of otherwise normal intrahepatic metabolism, results in reflux of conjugated bilirubin back into the circulation.

An important observation in DJS patients relates to the urinary excretion of coproporphyrins.[548,549] Patients with this disorder have an increase in the urinary excretion of coproporphyrin I with a concomitant decrease in the excretion of coproporphyrin III. This results in a total coproporphyrin excretion (I + III) that is normal or only slightly increased, but which consists of greater than 80% coproporphyrin I (normal 25%).[549-552] In heterozygotes the coproporphyrin I:III ratios are intermediate between normals and homozygotes,[549,551,552] though there is some overlap between heterozygotes and normals. The explanation for these findings regarding urinary coproporphyrin excretion is unclear. Several pathogenetic mechanisms have been suggested.[549] Fecal coproporphyrin levels are normal.[549] Healthy neonates have been shown to have impressive elevations of urinary coproporphyrin levels with more than 80% isomer I on the first 2 days of life.[553] By day 10, levels fell to overlap normal adult values.

Diagnosis and Treatment

A diagnosis of DJS should be considered in all individuals having elevation of conjugated bilirubin in the serum, along with otherwise normal liver function tests. The diagnosis can be confirmed by measuring urinary coproporphyrin levels of isomers I and III. While the total coproporphyrin level will be approximately normal, more than 80% will be isomer I. This finding is pathognomonic for DJS when congenital erythropoietic porphyria[554] or arsenic poisoning[555] have been excluded. Although oral cholecystogram may fail to visualize the gallbladder, ultrasound examination will show a normal biliary tree. Cholescintigraphy demonstrates prolonged intense visualization of the liver with delayed appearance of the gallbladder and only faint or nonvisualization of the biliary ducts.[511,556,557] Computed tomography of the liver has shown increased attenuation in one report.[558] Because cMOAT transport of leukotrienes into bile is defective in DJS, there is increased excretion of leukotriene metabolites into urine, and this has been suggested to be a new approach to the noninvasive diagnosis of this disease.[559] Another proposed diagnostic tool for DJS involves micro–positron emission tomography (microPET) imaging of a copper complex studied in normal and cMOAT-deficient (TR[-]) rats.[560] In normal rats, the radioactive copper complex was cleared quickly from the liver into the intestine, while radioactivity accumulated continuously in the liver of TR(-) rats and was not excreted into the small intestine.

Patients with DJS require no specific therapy. Although jaundice is a lifelong finding, it is associated with no morbidity or mortality, as demonstrated in a 30-year follow-up of 10 Japanese individuals.[541] Avoidance of the oral contraceptive has been recommended[561] because it can increase jaundice. Anticipatory guidance regarding pregnancy[527] is appropriate. Increased fetal wastage has been reported in one study.[562] In one case report of neonatal DJS with severe cholestasis, phenobarbital significantly decreased serum levels of bilirubin and bile acids,[520] though chronic phenobarbital therapy is not recommended.[563] Drugs such as rifampin and ursodeoxycholic acid should be used with caution if MRP2 expression is decreased, as in DJS.[564]

   Serum bilirubin patterns in humans and rats were studied. In Gilbert's syndrome, the concentration of unconjugated pigment was increased. Those with Crigler-Najjar had higher unconjugated bilirubin levels and undetectable diconjugated bilirubin. With hemolytic disease, the fraction of conjugated to total bilirubin remained within the normal range as both increased proportionally.
85. Poland RL, Odell GB: Physiologic jaundice: the enterohepatic circulation of bilirubin. *N Engl J Med* 284:1–6, 1971.

Bilirubin levels were evaluated after full-term infants were fed either a formula containing agar supplementation, a bilirubin stabilizer, or nonsupplemented formula for the first 5 days of life. The infants fed the agar-supplemented formula had no rise in serum bilirubin, excreted more bilirubin in their feces, and lost less weight than the nonsupplemented group. By day 6 of life, fecal bilirubin excretion was similar in each group. The authors concluded that the agar-stabilized bilirubin decreased enterohepatic circulation of bilirubin and subsequent elevations in serum bilirubin.

92. Gourley GR, Arend RA: β-glucuronidase and hyperbilirubinemia in breast-fed and formula-fed babies. *Lancet* i:644–646, 1986.

Bilirubin levels were studied in breastfed and formula-fed infants, with total serum levels significantly higher at both timepoints in the breastfed infants. Fecal studies at day 21 of life demonstrated higher β-glucuronidase levels in breastfed infants. β-glucuronidase activity was considerable in human milk and undetectable in formula and must be considered in the etiology of hyperbilirubinemia in breastfed infants.

95. Kreamer BL, Siegel FL, Gourley GR: A novel inhibitor of β-glucuronidase: L-aspartic acid. *Pediat Res* 50:460–466, 2001.

Infants who consume formulas with casein-hydrolysate, which contains a β-glucuronidase inhibitor, have lower bilirubin levels than their counterparts who are breastfed or regular formula-fed. The use of inhibition assays and kinetic studies demonstrated that the L-aspartic acid component of casein is responsible for β-glucuronidase inhibition.

96. Gourley GR, Li Z, Kreamer BL, et al: A controlled, randomized, double-blind trial of prophylaxis against jaundice among breastfed newborns. *Pediatrics* 116:385–391, 2005.

A group of 64 breastfed infants were randomized to receive supplements (6 mL 5 times daily) of either L-aspartic acid, enzymatically hydrolyzed casein (EHC), whey/casein (w/c), or a control group for the first week of life. Lower transcutaneous bilirubin levels were noted in the L-aspartic acid, EHC, and w/c groups versus the control group on days 3 to 7 of life and did not disrupt the breastfeeding experience. Fecal bile excretion was significantly greater in the L-aspartic acid group.

105. Schlebusch H, Axer K, Schneider C, et al: Comparison of five routine methods with the candidate reference method for the determination of bilirubin in neonatal serum. *J Clin Chem Clin Biochem* 28:203–210, 1990.

Five routine methods to determine serum bilirubin levels were compared to Doumas's reference method. Four of the methods (Jendrassik and Grof's method, Hertz's spectrographic, bilirubinometer procedure, and 2,5-dichlorophenyldiazonium method) produced higher values than the reference. A study of Vink's spectrographic method differed negligibly from the reference. Accuracy of some of the other methods could be improved with calibration.

In a group of 490 ethnically diverse, full-term and near-term infants, transcutaneous bilirubin levels were measured with a portable BiliChek device and found to correlate with total serum bilirubin values. In those infants with total serum bilirubin greater than the 95th percentile for age and at high risk, the transcutaneous bilirubin values were all greater than the 75th percentile for age.

120. Maisels MJ, Ostrea EM, Jr, Touch S, et al: Evaluation of a new transcutaneous bilirubinometer. *Pediatrics* 113:1628–1635, 2004.

In a group of 849 ethnically diverse, full-term and near-term infants, a close correlation was demonstrated between total serum bilirubin and transcutaneous bilirubin values as obtained by the Minolta-Hill-Rom Air-Shields Transcutaneous Jaundice Meter model. The correlation in black infants was less close (r = 0.822), with differences increasing with rising total serum bilirubin values, but the transcutaneous bilirubin value always overestimated the bilirubin levels.

121. American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 114:297–316, 2004.

In these guidelines by the AAP, it is proposed that successful breastfeeding be promoted and supported, infants should be systematically assessed for hyperbilirubinemia prior to discharge, follow-up should be dictated based on this assessment, and infants should be treated with phototherapy or exchange transfusion if dictated by levels of hyperbilirubinemia to prevent the development of adverse effects.

126. Odell GB, Schutta HS: Bilirubin encephalopathy. In McCandless DW, editor: *Cerebral energy metabolism and metabolic encephalopathy*, New York, 1985, Plenum Publishing Corp, pp 229–261.

This chapter discusses the typical clinical manifestations of kernicterus, histopathologic changes due to bilirubin injury, and treatment options.

129. Odell GB, Storey GNB, Rosenberg LA: Studies in kernicterus. III. The saturation of serum proteins with bilirubin during neonatal life and its relationship to brain damage at five years. *J Pediatr* 76:12–21, 1970.

In a group of 5-year-old children that were jaundiced during the neonatal period, psychometric studies were performed with 14 children classified as normal and 18 children classified as brain damaged. No correlations were found between brain damage and max serum bilirubin; however, a significant correlation was identified between brain damage and the saturation of serum proteins with bilirubin during the neonatal period.

132. Walker PC: Neonatal bilirubin toxicity-a review of kernicterus and the implications of drug-induced bilirubin displacement. *Clin Pharmacokinet* 13:26–50, 1987.

Interactions between bilirubin and common drugs given to newborn infants are reviewed in this article, including the methodology, mechanisms, and pharmacokinetics of various classes such as antibiotics, diuretics, and other commonly administered drugs.

140. Odell GB: The dissociation of bilirubin from albumin and its clinical implications. *J Pediatr* 55:268–279, 1959.

Bilirubin can be increased in the extracellular fluid by reducing the binding capacity of plasma proteins, such as albumin, for bilirubin. This is seen in premature infants due to hypoalbuminemia, and in full-term infants if decreased pH, or if sulfonamides, salicylates, or caffeine is present that reduces albumin's binding capacity, leading to hyperbilirubinemia.

155. Moyer V, Freese DK, Whitington PF, et al: Guideline for the evaluation of cholestatic jaundice in infants: recommendations of the north american society for pediatric gastroenterology, hepatology and nutrition. *J Pediatr Gastroenterol Nutr* 39:115–128, 2004.

A consensus statement for evaluation of cholestatic jaundice in infants was crafted after a comprehensive and systematic literature review, with recommendations for detection, pediatric gastroenterology referral, and management of jaundice. Infants who remain jaundiced at 2 weeks of age need evaluation of total and direct serum bilirubin. Breastfed infants with normal history and exam may defer serum determination of total and direct serum bilirubin until 3 weeks if jaundice persists.

159. Schneider AP: Breast milk jaundice in the newborn—a real entity. *JAMA* 255:3270–3274, 1986.

This pooled data analysis of 12 studies demonstrated that moderate and severe jaundice was significantly higher in breastfed versus formula-fed infants, breastfed infants have higher mean serum bilirubin levels, and that a significant relationship existed between jaundice and breastfeeding.

169. Gourley GR: Breast-feeding, neonatal jaundice and kernicterus. *Semin Neonato* l7:135–141, 2002.

In this review article, the author discusses mechanisms for the development of higher bilirubin levels in breastfed infants versus formula-fed infants, including poor fluid and caloric intake, inhibition of hepatic excretion of bilirubin, and enterohepatic circulation. With almost all of the cases of kernicterus in the last 15 years in full or partially breastfed newborns, this population should be followed closely.

201. Kaplan M, Renbaum P, Levy-Lahad E, et al: Gilbert syndrome and glucose-6-phosphate dehydrogenase deficiency: a dose-

dependent genetic interaction crucial to neonatal hyperbilirubinemia. *Proc Natl Acad Sci U S A* 94:12128–12132, 1997.

DNA from term neonates was analyzed for UDP-glucuronyltransferase-1 polymorphism and G6PD deficiency. Either one alone did not increase the incidence of hyperbilirubinemia, but in combination they did.

242. Bancroft JD, Kreamer B, Gourley GR: Gilbert syndrome accelerates development of neonatal jaundice. *J Pediatr* 132:656–660, 1998.

Gilbert's syndrome is usually diagnosed after puberty and has an unknown impact on neonatal jaundice. In 151 infants transcutaneous bilirubin measurements were taken, and genomic analysis of the UGT1A promoter of the gene for bilirubin UDP-glucuronosyltransferase (BUGT) was performed to evaluate for polymorphisms associated with Gilbert's syndrome (A$(TA)_7$*TAA polymorphism). The 13% of subjects homozygous for the Gilbert-associated polymorphism had a greater increase in jaundice versus heterozygotes or those without the polymorphism in the first 2 days of life.*

266. Bosma PJ, Chowdhury JR, Bakker C, et al: The genetic basis of the reduced expression of bilirubin UDP-glucuronosyltransferase 1 in Gilbert's syndrome. *N Engl J Med* 333:1171–1175, 1995.

The coding and promoter regions of the gene for bilirubin UDP-glucuronosyltransferase 1 were sequenced in patients with Gilbert's syndrome, Crigler-Najjar type II, and normal subjects. Abnormalities were noted in the promoter region of the gene in those with Gilbert's, encoding two extra bases in the TATAA element. This promoter region abnormality appeared to be necessary but not sufficient for complete manifestation of the Gilbert's syndrome.

295. Bartlett MG, Gourley GR: Assessment of UGT polymorphisms and neonatal jaundice. *Semin Perinatol* 35:127–133, 2011.

This is a review of the current understanding of genetic polymorphisms of bilirubin conjugation that lead to Gilbert's syndrome and Crigler-Najjar syndrome. In white populations, a $(TA)_7$*TAA repeat in the promoter region of the UGT1A1 is a necessary although not sufficient condition for GS. In Asian populations, mutations have been identified in exon 1 of the UGT1A1 gene rather than the promoter region. In Crigler-Najjar, functional UGT1A1 is absent in type I, or markedly reduced in type II.*

399. Kawade N, Onishi S: The prenatal and postnatal development of UDP-glucuronyltransferase activity towards bilirubin and the effect of premature birth on this activity in the human liver. *Biochem J* 196:257–260, 1981.

Liver UDP-glucuronyltransferase activity was studied in a number of human subjects and divided into four developmental phases of middle fetal, late fetal, neonatal, and mature. Activity was significantly lower in the early phases compared to the mature phase (0.1%, 0.1% to 1%, and 1% to 100% respectively).

404. Johnson L, Brown AK: A pilot registry for acute and chronic kernicterus in term and near-term infants. *Pediatrics* 104:736, 1999.

A pilot kernicterus registry from 21 states was analyzed, and characteristics that put infants at risk for kernicterus were identified. It identifies the reemergence of kernicterus in a small subset of otherwise healthy-appearing newborns due to early disharge, and lack of mandated early follow-up, as well as lactation counseling.

415. Maisels MJ, Newman TB: Kernicterus in otherwise healthy, breast-fed term newborns. *Pediatrics* 96:730–733, 1995.

Cases of neonatal hyperbilirubinemia alleged to be responsible for brain damage were reviewed in apparently healthy, full-term newborns. Six infants were inluded in analysis and had no evidence of hemolysis, and no other cause identified, other than breastfeeding.

CHAPTER OUTLINE

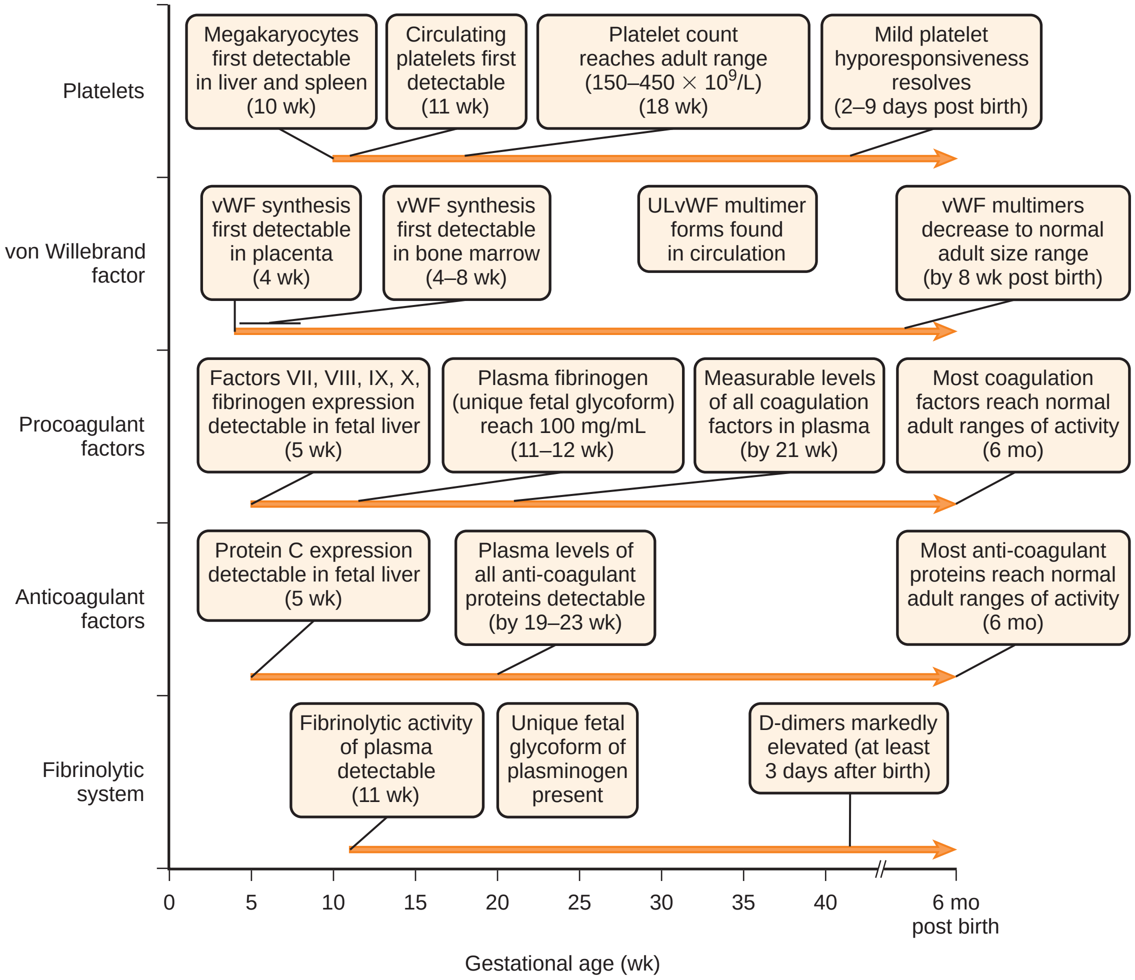
ONTOGENY OF THE HUMAN HEMOSTATIC SYSTEM
Coagulation Factors
Natural Inhibitors of Coagulation
Vitamin K–Dependent Factors
The Fetal and Neonatal Fibrinolytic System
D-Dimers
von Willebrand Factor
Platelets
Blood Vessel Wall: Age and Anticoagulant Properties
Maternal Preeclampsia and Fetal Hemostasis
Summary of Hemostatic Differences between Neonates and Older Children and Adults
CLINICAL ASPECTS OF DEVELOPMENTAL HEMOSTASIS
Hemorrhagic Disorders in the Neonate
Thrombotic Disorders in the Neonate
CONCLUSION

Development of the human hemostatic system begins in utero and continues until well after birth. As a result, functional levels of many of the procoagulants, coagulation inhibitors, fibrinolytic components, and platelet-associated factors differ from those of older children and adults, with "adult" values often not reached until about 6 months of age. These unique aspects of fetal and neonatal coagulation were first fully documented in the pioneering work of Dr. Maureen Andrew in the 1980s and have been termed *developmental hemostasis*. A firm understanding of these differences, as well as access to the "normal" ranges of various hemostatic factors in infants at different gestational and postnatal ages, is critical to proper interpretation of laboratory tests performed on newborns and infants. Despite broad differences from adults in functional levels of hemostatic factors, healthy newborns rarely have difficulties with hemorrhage or thrombosis. Thus these differences in prothrombotic and antithrombotic factors are uniquely balanced in the neonate and fetus and represent a normal physiologic state. However, this system provides little reserve, which often contributes to significant morbidity in sick and preterm infants. In addition to these developmental aspects of hemostasis, many inherited bleeding and clotting disorders can present in the newborn period. This chapter describes the normal development of the hemostatic system and reviews disorders of hemostasis and thrombosis that can occur in the newborn period. Data tables listing normal ranges of hemostasis laboratory tests for term and preterm infants are included in the Appendix. For additional discussion of the investigation and management of neonatal hemostasis and thrombosis, see several recent evidence-based guidelines.[1,2]

ONTOGENY OF THE HUMAN HEMOSTATIC SYSTEM

Coagulation Factors

The biochemistry and function of the individual coagulation factors are reviewed in detail in Chapter 27. Coagulation proteins do not effectively cross the placental barrier and are independently synthesized by the fetus.[3-15] Messenger RNA (mRNA) transcripts for coagulation factors VII, VIII, IX, and X and fibrinogen are detectable at about 5 weeks of gestation in hepatocytes of the embryo (Fig. 5-1).[16] By 10 weeks of gestation, plasma protein levels of most factors are measurable but range from 10% of the normal adult level for factor IX to about 30% for most of the other coagulation factors.[17] In general, these levels continue to increase gradually in parallel with gestational age (Appendix Table A5-1). However, with the exception of fibrinogen and factors V, VIII, and XIII, these levels remain considerably below the normal adult range, even at the time of birth for full-term infants.[17,18-23,24,25] They then continue to gradually increase and reach the normal adult range by about 6 months of age (Appendix Tables A5-2 and A5-3). Premature infants have an accelerated increase in levels after birth and, in



Platelets
Megakaryocytes first detectable in liver and spleen (10 wk)
Circulating platelets first detectable (11 wk)
Platelet count reaches adult range (150–450 × 10⁹/L) (18 wk)
Mild platelet hyporesponsiveness resolves (2–9 days post birth)
von Willebrand factor
vWF synthesis first detectable in placenta (4 wk)
vWF synthesis first detectable in bone marrow (4–8 wk)
ULvWF multimer forms found in circulation
vWF multimers decrease to normal adult size range (by 8 wk post birth)
Procoagulant factors
Factors VII, VIII, IX, X, fibrinogen expression detectable in fetal liver (5 wk)
Plasma fibrinogen (unique fetal glycoform) reach 100 mg/mL (11–12 wk)
Measurable levels of all coagulation factors in plasma (by 21 wk)
Most coagulation factors reach normal adult ranges of activity (6 mo)
Anticoagulant factors
Protein C expression detectable in fetal liver (5 wk)
Plasma levels of all anti-coagulant proteins detectable (by 19–23 wk)
Most anti-coagulant proteins reach normal adult ranges of activity (6 mo)
Fibrinolytic system
Fibrinolytic activity of plasma detectable (11 wk)
Unique fetal glycoform of plasminogen present
D-dimers markedly elevated (at least 3 days after birth)

Figure 5-1 Development of the hemostasis system in human embryos and newborns. Reported detection or other key developmental changes that occur in the different components of the hemostatic system during gestation and the first 6 months of postnatal life are presented in this schematic timeline. *ULVWF*, ultralarge von Willebrand factor multimers. *(Modified from Manco-Johnson MJ: Development of hemostasis in the fetus.* Thromb Res *115[Suppl 1]:55–63, 2005.)*

general, "catch up" to the full-term infant range by 3 months' postnatal age (Appendix Table A5-4).[26] True reference ranges for extremely premature infants (<30 weeks' gestation) are not available, because the majority of these infants have postnatal complications. Appendix Table A5-5 provides reference ranges for older children.[22] The nearly normal "adult" levels of fibrinogen and factors V and VIII in neonates make them useful markers for the investigation of possible consumptive coagulopathy or hemophilia A.

Regulation of fetal coagulation protein levels occurs by both transcriptional and posttranscriptional mechanisms.[16,27] In addition, ratios of hepatocyte levels to plasma levels of many factors are relatively high in comparison with adults, suggesting that delayed hepatocyte release may also contribute to the relatively low coagulation factor levels in fetuses and newborns.[28]

Qualitative differences in procoagulant proteins also exist between neonates and adults. Fibrinogen from fetuses has increased sialic acid content, increased phosphorus content, and different chromatographic profiles compared with fibrinogen from adults.[29-32]

Natural Inhibitors of Coagulation

Like many of the procoagulant factors, functional levels of most coagulation inhibitors in fetuses and neonates are significantly lower than those in adults (Appendix Tables A5-6 and A5-7; see also Appendix Table A5-3).[17,19-21] Awareness of these differences is critical to proper interpretation of laboratory studies obtained during evaluation of neonatal thrombosis. Most coagulation inhibitors reach the adult range of activity by 6 months of age.

As reviewed in Chapter 27, at least three mechanisms/pathways exist for inhibition of procoagulant activity: (1) cleavage of factors V and VIII by the protein C/S system; (2) direct inhibition of thrombin by antithrombin (AT), heparin cofactor, and α_2-macroglobulin; and (3) inhibition of factor VIIa by the tissue factor pathway inhibitor (TFPI)/factor Xa complex. When thrombin binds to thrombomodulin on endothelial surfaces, it no longer cleaves fibrinogen but it activates protein C. Activated protein C, in complex with protein S, proteolytically inactivates factors V and VIII. At birth, plasma concentrations of protein C are quite low and remain decreased during the first 6 months of life.[18,20,21,26] Neonates also have about a twofold higher amount of the single-chain form of protein C than adults do, and they may exhibit increased protein C glycosylation. Despite these alterations, there is no evidence that protein C from neonates differs functionally from that of adults when compared at equivalent concentrations.[33,34]

In adults, protein S circulates in either a free form or in a form that is bound to the carrier protein C4b binding protein. In fetuses and neonates, circulating protein S is almost entirely of the free type because levels of C4b binding protein are extremely low.[35,36] Thus the protein S activity-to-antigen ratio is greater for fetuses and neonates than for adults. Nonetheless, both total and free protein S levels are lower in fetuses and neonates. They rise gradually after birth, with the adult range of free protein S reached by 4 months and total protein S by about 10 months.[1] The interaction of protein S with activated protein C in the plasma of newborns may be modulated by increased levels of α_2-macroglobulin.[37]

Healthy full-term newborns have lower functional AT levels than adults do, with an average of 0.55 U/mL based on several studies.[13,14,19,20,38-41] This is most likely due to a reduced amount of absolute AT protein inasmuch as most studies have found no significant difference in the antigen-to–functional activity ratio or the immunoelectrophoretic or chromatographic properties of purified AT from neonates and adults.[13,38,41,42] The reduced AT levels in neonates probably account, at least in part, for the relative heparin resistance seen in this age group. AT levels typically reach the adult range by 3 months of age in full-term healthy infants. Preterm infants with respiratory distress syndrome (RDS) have significantly lower levels of AT, typically less than 0.2 U/mL, and the AT present often has additional dysfunctional properties.[38,43-46] Lower AT levels correlate with increased catheter-related thromboses, intracranial hemorrhages (ICH), and mortality rates.

Like AT, levels of heparin cofactor II are also substantially lower in infants than adults.[47] A circulating fetal dermatan sulfate proteoglycan has been described that has natural anticoagulant properties mediated through heparin cofactor II.[48] This fetal anticoagulant is also present in the plasma of pregnant women and is produced by the placenta. The length of time that it circulates in newborns is not known; however, it is still present during the first week of life in sick premature infants with RDS.

α_2-Macroglobulin is a more important inhibitor of thrombin in plasma from newborns than in adults.[49] It compensates, in part, for the low levels of AT and heparin cofactor in newborns, even in the presence of endothelial cell surfaces.[49,50] However, the overall rate of thrombin inhibition is still lower in newborns than adults.[49]

TFPI binds to factor VIIa/tissue factor complexes in a factor Xa calcium-dependent reaction that results in the inhibition of factor VIIa. After generation of small amounts of thrombin, TFPI prevents further generation of thrombin via tissue factor/factor VIIa. TFPI levels in cord plasma have been reported to be approximately 50% of adult values.[51]

Vitamin K–Dependent Factors

Factors II, VII, IX, and X and proteins C, S, and Z undergo posttranslational γ-carboxylation dependent on vitamin K (VK) of certain glutamic acid residues (see Chapter 27). Typically, 9 to 12 glutamic acid residues, often clustered within a 45–amino acid region referred to as the "Gla" domain, are modified.[28,52] γ-Carboxylation of glutamic acids enhances calcium-dependent phospholipid interactions of the coagulation factors and helps regulate the coagulation cascade. Because of the association of relative VK deficiency and hemorrhagic disease of the newborn (HDN; see detailed description later), development of these VK-dependent factors in utero has been the focus of considerable research. During gestation, a steep gradient of VK concentration is maintained across the placenta, with fetal levels being 10% or less of maternal levels.[28,53-58] This gradient is even further enhanced during the third trimester.[54] Consequently, VK stores in newborns are low, as shown by low levels of VK in the cord blood and liver of aborted fetuses and increases in VK-dependent coagulation factor activity following VK administration to neonates.[53,56,59,60] The teleologic explanation for maintenance of low fetal VK levels is not known. However, VK has been shown to promote DNA mutagenesis in vivo. For this reason, several investigators have suggested that maintenance of low fetal VK levels might be a mechanism to prevent chromosomal damage during the rapid cellular proliferation of embryogenesis.[61-63] In addition to these low VK levels, deficiency of VK reductase activity (a rate-limiting step in the reaction) as a result of immaturity of the hepatocyte may contribute to inefficient γ-carboxylation of coagulation factors.[28] In fact, undercarboxylated prothrombin and protein C have been detected in the cord and peripheral blood of up to 7% and 27% of healthy term infants, respectively, and these levels correlate with gestational age.[64,65] Even when corrected for this relative VK deficiency, levels of VK-dependent factors are still considerably lower than the normal adult range because the values presented in Appendix Tables A5-1 to A5-4, A5-6, and A5-7 were measured in infants who received VK prophylaxis at birth.

VK-dependent glutamic acid carboxylation also occurs on proteins outside the coagulation system, many of which play roles in development. Such proteins include Gas-6, the ligand for the receptor kinases Sky and Axl; the bone growth–related and calcification-related factors osteocalcin and matrix Gla protein; the urine calcium binding protein nephrocalcin; and PRPG1 and PRPG2, two proline-rich predicted signaling proteins expressed in the central nervous system and endocrine tissues.[52,65-67] Thus VK is predicted to have pleiotropic effects on development.

Although VK is maintained at low levels in the fetus, further deficiency of VK during gestation can reduce functional levels of the VK-dependent coagulation factors to an even greater extent. Maternal use of certain anticonvulsant medications, including phenytoin, phenobarbital, valproic acid, and carbamazepine, is associated with an increased risk of VK deficiency in the fetus and neonate.[28,68] Fetal or neonatal bleeding has been linked to maternal use of these medications on rare occasions. Fetal VK deficiency can be prevented in such cases by antenatal oral administration of 10 mg of VK_1 daily to the mother beginning at 36 weeks' gestation.[69]

Warfarin is a potent VK antagonist commonly used for long-term anticoagulation. It crosses the placenta and inhibits VK-dependent carboxylation in the fetus. Its use during pregnancy at 6 to 12 weeks of gestation is associated with an embryopathy syndrome consisting of limb deformities, nasal hypoplasia, ophthalmologic malformations, mental retardation, hypotonia, and ear abnormalities.[70] Warfarin exposure during the second or third trimester is associated with fetal wastage and central nervous system anomalies. The developmental defects related to warfarin use during pregnancy are thought to be due to bleeding into the developing limb buds or effects on bone and cartilage growth from inhibition of bone-associated Gla proteins, or both.

The Fetal and Neonatal Fibrinolytic System

The enzyme plasmin degrades polymerized fibrin and is responsible for clot dissolution. It is generated from its precursor plasminogen by two known activators, tissue plasminogen activator (tPA) and urokinase plasminogen activator. These activators, in turn, are inhibited by the plasminogen activator inhibitors PAI-1 and PAI-2. In addition, plasmin itself is inhibited by the circulating blood protein α_2-antiplasmin. See Chapter 28 for a more detailed description of the fibrinolytic system. In newborns, plasminogen levels are only 50% of adult values, α_2-antiplasmin levels are 80% of adult values, and plasma concentrations of PAI-1 and tPA are significantly greater than adult values (Appendix Table A5-8).[18,20,21,26,71,72,73,74] The increased levels of tPA and PAI-1 found on day 1 of life contrast markedly with values obtained from cord blood, which are significantly lower than adult levels. The discrepancy between newborn and cord plasma concentrations of tPA and PAI-1 may be explained by the enhanced release of both proteins from the endothelium shortly after birth. PAI-2 levels are detectable in cord blood but are significantly lower than they are in pregnant women.[75] Unique glycoforms of plasminogen with an increased content of mannose and sialic acid exist in the fetus.[76-78] This fetal form of plasminogen is less efficiently converted to plasmin by tPA compared with adult plasminogen.[76] No significant differences exist in activation kinetics by urokinase plasminogen activator.[76]

D-Dimers

D-dimers are the breakdown product of fibrin mesh cross-linked by factor XIII. Neonates have markedly elevated D-dimer levels in comparison with older children and adults that persist for at least 3 days after birth (Appendix Table A5-9).[19] These high levels suggest activation of the coagulation system at birth or decreased clearance of D-dimers in neonates, or both.

von Willebrand Factor

von Willebrand factor (VWF) is a large protein that mediates adhesion of platelets to exposed subendothelium and is involved in platelet aggregation (see Chapter 26). Its synthesis can first be detected as early as 4 weeks of gestation in placental endothelial cells and by 4 to 8 weeks in bone marrow.[28,79,80] In contrast to other coagulation factors, VWF functional levels are considerably elevated in neonates in comparison with the normal adult range (see Appendix Tables A5-2 and A5-5). They gradually decline to the normal adult range by about 3 to 6 months. It is important to keep these physiologically elevated levels in mind when using VWF as a marker of inflammation in infants.

VWF is released from endothelial cells and megakaryocytes as large multimers with molecular weights in the millions-of-dalton range. They are then cleaved into smaller multimers by the metalloproteinase ADAMTS-13. Unusually large VWF (ULVWF) multimers are VWF multimer forms larger than those found in normal plasma. These ULVWF multimers are 10 to 20 times more active in shear stress–induced platelet aggregation and bind more avidly to the extracellular matrix of fibroblasts than do the VWF multimer forms found in normal plasma.[81,82] In older children and adults, the presence of ULVWF plasma forms is the hallmark of thrombotic thrombocytopenic purpura, a microangiopathic disorder. It is due to deficiency, acquired or congenital, of ADAMTS-13. ULVWF forms are consistently found in platelet-poor plasma (PPP) from fetuses less than 35 weeks' estimated gestational age (EGA) and most fetuses older than 35 weeks' EGA, as well as in umbilical cord blood.[83,84] These forms are not seen in simultaneously sampled maternal PPP, indicating that the ULVWF forms are fetal specific. The ULVWF in fetal PPP is similar to the VWF directly released from endothelial cells. This similarity may be explained by the finding of low VWF cleaving protease (ADAMTS-13) activity in many neonates.[85,86] Serial monitoring of PPP from neonates shows a gradual reduction in ULVWF to the normal size range within 8 weeks after birth.[84] The presence of ULVWF during fetal development is probably physiologically relevant because plasma derived from umbilical cord blood shows increased shear stress–induced and ristocetin-induced VWF platelet-binding activity in comparison with plasma derived from adults, even when adult platelets are used in the assay.[87] The enhanced hemostatic efficacy of ULVWF may therefore partially balance the low functional levels of other coagulation factors to achieve reliable hemostasis in the fetus and newborn.

Platelets

Megakaryocytes During Fetal Development

In humans, megakaryocytes are first detectable in the liver and spleen by 10 weeks of gestation.[88] By 30 weeks, megakaryocytes are present in bone marrow and actively contribute to thrombopoiesis. Circulating megakaryocyte progenitors are detectable in the blood of neonates, and their number decreases as a function of postconceptional age (gestational age plus days of life).[89] Neonatal megakaryocytes have distinct properties compared with adult megakaryocytes, including increased thrombopoietin sensitivity, increased proliferation, lower ploidy, and increased cytoplasmic maturation for the degree of ploidy.[90] The differences in megakaryocyte size resolve by about 4 years of life.[91]

Platelet Number, Size, and Survival During Development

In humans, circulating platelets are first detected by 11 weeks' gestational age.[88] Thereafter, the plasma platelet concentration rises rapidly and reaches the adult range of 150 to 450 × 10^9/L by about 18 weeks of gestation.[21,28,72,88,92-98] During the earliest phase of platelet production, mean platelet volume is larger than the adult range.[28] However, platelet volume "normalizes" soon thereafter and reaches the adult range of 7 to 9 fL.[99,100] It is possible that the larger platelets arise from a unique wave of "primitive" megakaryopoiesis that occurs early in gestation, as demonstrated in several mouse studies,[101,102] but this mechanism remains to be determined in humans. Platelet survival has not been measured in healthy infants. In rabbits, survival of ^{111}In-oxine–labeled platelets is similar in adult and newborn rabbits.[103] However, in humans, levels of reticulated platelets, which represent those recently released from megakaryocytes, are elevated about twentyfold in comparison with adults.[104] Concentrations of thrombopoietin (TPO), the major cytokine for megakaryocyte progenitor proliferation and development, are increased about twofold in fetal versus adult plasma.[105] These findings suggest possible increased platelet turnover in human fetuses versus adults.

Platelet Structure

Peripheral blood platelets from newborns contain similar numbers of platelet-specific granules as platelets from older children and adults; however, serotonin and adenosine diphosphate (ADP), which are stored in dense granules, are present at concentrations of less than 50% of adult values.[106] Newborn platelets contain normal levels of the receptors glycoprotein Ib (GPIb) (part of the VWF binding complex), GPIa/IIa, P-selectin, and HPA-1a. Variable levels of GPIIb/IIIa have been reported, with some studies indicating significantly reduced expression.[107,108] Functional epinephrine receptors are significantly diminished in newborn platelets.[109]

Platelet Function

Platelet aggregometry and other functional assays of neonatal and cord blood platelets have shown variable results, but most demonstrate a modest hyporesponsiveness to ADP, epinephrine, collagen, and thrombin when compared with platelets from older children and adults (Fig. 5-2).[107,110-118] The hyporesponsiveness spontaneously resolves by 2 to 9 days after birth in full-term infants.[119] Extremely low birth weight neonates (<1 kg, gestation < 30 weeks) have markedly hyporesponsive platelets.[114,120] This impaired platelet response may contribute to the propensity of extremely low birth weight neonates for ICH. The platelet hyporesponsiveness improves over the

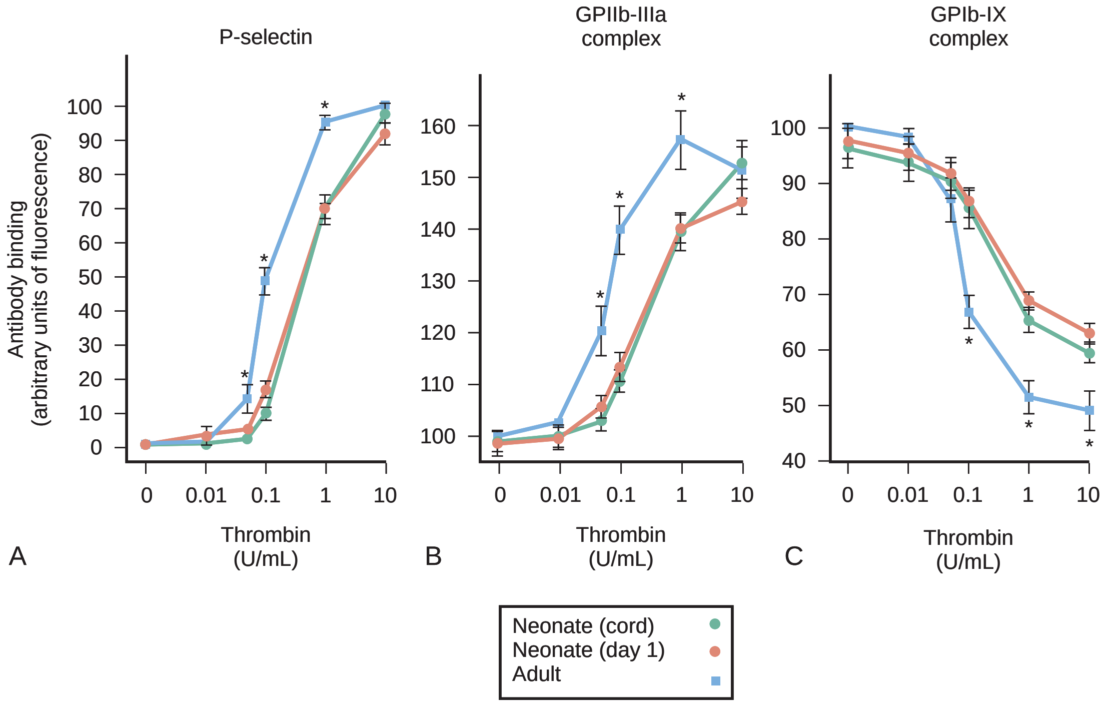

Figure 5-2 Effect of thrombin on the surface expression of P-selectin, the glycoprotein (GP) IIb/IIIa complex, and the GPIb/IX complex on neonatal and adult platelets in whole blood. Results were similar for cord blood and neonatal day 1 platelet values. Expression of P-selectin and GPIIb/IIIa complexes was decreased in newborns, whereas GPIb/IX expression was relatively well preserved in newborns in comparison with adults after stimulation with thrombin. Data are expressed as means ± SEM; $N = 20$. *Asterisks* indicate $P > .05$ for both cord blood and day 1 neonatal platelets in comparison with adult platelets. *(Redrawn from Rajasekhar D, Kestin AS, Bednarek FJ, et al: Neonatal platelets are less reactive than adult platelets to physiological agonists in whole blood.* Thromb Haemost *72:957–963, 1994.)*

first 10 to 14 days after birth, but platelet reactivity does not reach adult levels even by day 14.[114] Several explanations have been proposed to account for this hyporesponsiveness, including impaired calcium channel transport and signal transduction,[121-124] decreased availability of α-adrenergic receptors because of either delayed receptor maturation or occupation by catecholamines released during birth,[106,110,111,113,121,125-128] and the presence of inhibitory placenta-derived prostaglandins.[129]

In contrast to the agonists just described, agglutination in response to low concentrations of ristocetin is significantly enhanced in fetal and newborn platelet-rich plasma in comparison with that of adults,[106] probably partly because of high VWF levels and the presence of ULVWF forms in newborn plasma.[83,84,121,130-132] In the end, the hyporesponsiveness to certain platelet agonists and the hyperresponsiveness to VWF appear to balance each other out inasmuch as most healthy term infants do not experience bleeding or thrombotic complications in the newborn period.

Platelet Activation During the Birth Process

There is strong evidence that platelets are activated during the birth process. Cord plasma levels of thromboxane B_2, β-thromboglobulin, and platelet factor 4 are increased; the granular content of cord platelets is decreased; and epinephrine receptor availability is reduced, perhaps as a result of occupation.[133-136] The mechanisms of activation are probably multifactorial and include thermal changes, hypoxia, acidosis, adrenergic stimulation, and the thrombogenic effects of amniotic fluid.

Blood Vessel Wall: Age and Anticoagulant Properties

The endothelium fulfills a complex role in hemostasis in that it prevents thrombotic complications under physiologic conditions and promotes fibrin formation when injured. One of the anticoagulant properties of endothelial cell surfaces is mediated by lipoxygenase and cyclooxygenase metabolites of unsaturated fatty acids. Prostacyclin (prostaglandin I_2) production by cord vessels exceeds that by blood vessels in adults.[137] A second endothelial cell–mediated antithrombotic property is promotion of AT neutralization of thrombin by cell surface proteoglycans. Structurally, there is evidence that the vessel wall glycosaminoglycans of the young differ from those of adults.[138,139] In a rabbit venous model, increased amounts of glycosaminoglycans are seen in the inferior venae cavae of rabbit pups as compared with adults. Similarly, in the rabbit arterial model, greater glycosaminoglycan-mediated AT activity is seen in rabbit pups than in adult rabbits.[140,141]

Maternal Preeclampsia and Fetal Hemostasis

Preeclampsia is a pregnancy-associated syndrome consisting of maternal hypertension and proteinuria. Alterations in maternal coagulation and fibrinolysis, including reduced AT and PAI-2 levels and increased tPA antigen, PAI-1 antigen, and fibrin degradation product levels, have been described in women with preterm preeclampsia.[142-146] This suggests a state of enhanced thrombin generation and fibrinolysis in the maternal circulation. Analysis of cord blood from infants born to mothers with preeclampsia shows no statistical difference in the levels of these factors versus those of age-matched controls born to mothers without preeclampsia, thus indicating a probable protective effect of the placenta on the fetal circulation.[142,147]

Summary of Hemostatic Differences Between Neonates and Older Children and Adults

In summary, the salient differences in the hemostatic system of neonates and older children or adults are (1) decreased plasma concentrations of many of the procoagulant proteins, including factors II, VII, IX, X, XI, and XII, prekallikrein, and high–molecular-weight kininogens; (2) a unique fetal glycoform of fibrinogen; (3) decreased plasma concentrations of the coagulation inhibitors AT, heparin cofactor II, TFPI, protein C, and protein S, with a concomitantly slower rate of thrombin inhibition; (4) a unique glycoform of plasminogen that is less efficiently converted to plasmin by tPA; (5) markedly elevated D-dimer levels until at least 3 days after birth; (6) increased plasma VWF concentrations and elevated levels of circulating ULVWF multimers; (7) smaller and more proliferative megakaryocytes; and (8) modest, transient hyporesponsiveness of platelets to certain agonists such as collagen and epinephrine, but increased agglutination with low-dose ristocetin. In general, most of these differences resolve within the first 6 months of life.

CLINICAL ASPECTS OF DEVELOPMENTAL HEMOSTASIS

Hemorrhagic Disorders in Neonates

Although acquired disorders are more commonly seen, severe forms of congenital factor deficiencies or platelet disorders can present in early infancy and should be seriously considered in otherwise healthy infants who are bleeding.[28,43,148-151] About 15% to 30% of children with inherited bleeding disorders have hemorrhage in the neonatal period.[152,153] In addition, a third of new cases of severe hemophilia represent new mutations and are therefore not accompanied by any antecedent family history.[153]

Clinical Findings

The clinical manifestations of bleeding disorders are different in newborns than in older children and adults. Bleeding may appear as oozing from the umbilicus, bleeding into the scalp, large cephalhematomas, bleeding after circumcision, bleeding from peripheral phlebotomy sites, and bleeding into the skin. A small but important proportion of infants are seen with ICH as the first manifestation of their bleeding tendency.[151,154-160] Sick infants can bleed from mucous membranes, the bladder, and sites of invasive procedures. Joint bleeding is rare. The most common causes of bleeding in healthy infants are thrombocytopenia secondary to transplacental passage of a maternal antiplatelet antibody, sepsis, VK deficiency, and congenital coagulation factor deficiencies.

Laboratory Evaluation

In addition to a workup for sepsis, laboratory evaluation of infants with bleeding complications should include determination of the prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin clotting time (TCT), fibrinogen level, and platelet count. As discussed earlier, results need to be compared with the expected range of values for neonates because some may not reflect the normal adult range. It is also critical to apply age-specific reference ranges generated using the same analyzer and reagents because these can influence the measured absolute levels.[161] Tests that provide exogenous AT should be avoided because they do not reflect the normal physiologic state of low AT levels in neonates. Values obtained from cord blood may be different from those obtained from neonatal peripheral blood samples.[32] Abnormalities in test results usually prompt additional tests, such as specific factor assays. For a male child in whom hemophilia A or B is suspected, specific factor assays should be performed regardless of the APTT value. The PT, APTT, and TCT are not prolonged in those with factor XIII and α_2-antiplasmin deficiency. Therefore levels of these factors must be measured directly if deficiencies are suspected.

Sample Collection. Collection of samples for laboratory investigation of hemostatic defects in neonates, especially premature infants, presents particular challenges because of the patient's small size and increased hematocrit. Specialized microcollection tubes (1 mL) should be available in the neonatal unit. Blood sampling techniques should avoid contamination with intravenous fluids and heparin and should also avoid activating the coagulation system. Slow transit time and contact with plastic tubing are most likely to cause activation. All neonatal samples should be inspected for the presence of fibrin clumps before processing, and those containing clumps should not be used for analysis. Ideally, the volume of anticoagulant in the sample should be based on the volume of plasma, not the total volume of blood, because the increased hematocrit of neonates causes accentuated dilution of the coagulation factors if not taken into account.[1] This is particularly important for neonates with very high hematocrit values, such as those with cyanotic congenital cardiac disease. Overfilled or underfilled samples should not be analyzed.

Screening Coagulation Tests in Neonates. Screening tests of plasma clotting activity, including the PT, APTT, and TCT, are all prolonged during fetal development and in neonates when compared with the normal adult range (see Appendix Tables A5-1 to A5-3), probably because of physiologic "deficiencies" of the VK-dependent factors and contact factors and the presence of fetal glycoforms of fibrinogen.[1] The absolute values for these tests, as well as specific coagulation factor tests, depend on the reagents and analyzer used. Appendix Table A5-3 provides reference ranges using the STA Compact analyzer and Diagnostica Stago reagents, a system currently used in many clinical laboratories.[19] In contrast to some earlier systems, such as the ACL system, the STA Compact analyzer is not affected by plasma bilirubin levels, which are frequently elevated in neonates. Reference ranges using the Behring Coagulation System (BCS) and the Sysmex CA-1500 System with various reagents have also recently been published.[20] The differences observed underscore the need for each clinical laboratory to establish its own normal age-related reference ranges.[19]

Bleeding Time. The bleeding time has traditionally been used as an in vivo test of platelet function, particularly for testing adhesion to injured vasculature.[130] However, it is subject to considerable operator-dependent variability and is not routinely used in newborns. Automated devices modified for newborns and children are available and have been standardized.[162] In contrast to the prolonged coagulation screening tests, multiple studies have shown that bleeding times in infants during the first week of life are significantly shorter than those in adults.[121,130-132,162,163] This somewhat paradoxic finding can be explained by several mechanisms, including higher plasma concentrations of VWF,[18,21,26] enhanced function of VWF because of a disproportional increase in ULVWF multimers,[83,84] large red cells,[164] and high hematocrits.[165]

Platelet Function Analyzer. The Platelet Function Analyzer 100 (PFA-100) system provides an in vitro method of assessing primary platelet-related hemostasis by measuring the time (closure time) required for a platelet plug to occlude a microscopic aperture cut into a membrane coated with collagen and either epinephrine or ADP. It uses the patient's own platelets and plasma. The PFA-100 system is attractive for use in neonates because of the small volume required, rapidity of testing, and standardization of testing cartridges. Like the bleeding time, most studies of neonates' peripheral or cord blood report PFA-100 closure times, for both epinephrine and ADP, that are shorter than those for older children and adults (Appendix Table A5-10).[1,166-170] This is probably due to similar mechanisms as described earlier for the shortened bleeding time.[167] Ranges for premature infants have been reported and show an inverse relationship between ADP closure time and gestational age.[170] Although the PFA-100 system may eventually become a standard screening test for platelet function in neonates, older children, and adults, its clinical utility has not yet been clearly established.[171] Thus further studies will be required to determine the optimal method of assessing primary hemostasis in newborns and children, particularly premature infants.

Hereditary Coagulation Factor Deficiencies

For most hemostatic components, both severe and mild forms of deficiency can occur, with severe deficiencies often characterized by significant bleeding in newborns. Chapters 31 and 32 discuss hereditary factor deficiencies in detail.

Inheritance. Deficiencies of factors II, V, VII, XI, and XII, prekallikrein, and high–molecular-weight kininogen are rare autosomally inherited disorders, with consanguinity present in many families. Deficiencies of factor XII, prekallikrein, and high–molecular-weight kininogen do not result in hemorrhagic complications and thus are not considered further here. Deficiencies of factors VIII and

IX are sex linked and the most common congenital bleeding disorders to present in newborns. Rarely, combined deficiencies of factors II, VII, and IX and/or factors V and VIII may also present in the neonatal period.[172-174] Tests are available to diagnose most congenital factor deficiencies prenatally so that either termination of pregnancy or management of affected infants can be planned (see Chapters 31 and 32).

Clinical Findings. In the majority of newborns with congenital coagulation factor deficiencies, bleeding does not occur in the perinatal period unless a hemostatic challenge is present. On the other hand, unexplained bleeding in an otherwise healthy newborn should be carefully investigated because it may be due to a congenital coagulation factor deficiency.

ICH is rare in full-term newborns and usually occurs either spontaneously or after insults such as birth asphyxia or trauma, VK deficiency, or severe congenital factor deficiencies. Other risk factors include low birth weight, young gestational age, and ethnic background.[175-183] The risk for ICH in children with severe hemophilia A or B ranges from 2% to 8%. The location of the ICH is most commonly the subarachnoid area, but subdural and parenchymal bleeding also occurs. Head ultrasound may not detect small parafalcine or subdural bleeding, so computed tomography or magnetic resonance imaging is the preferred modality when deficiency of a coagulation factor is suspected.[184] Some infants require surgical intervention, and many have long-term neurologic deficits.

Full-term infants with unexplained ICH should be carefully evaluated for congenital or acquired hemostatic defects. Unfortunately, the diagnosis of ICH may be delayed because of the nonspecific nature of the early clinical findings, including poor feeding, lethargy, apnea, vomiting, and irritability. Further delays can result when secondary coagulopathies such as disseminated intravascular coagulation (DIC) occur or because of confusion related to the physiologically low levels of some coagulation factors in newborns.[185,186] The more extreme clinical manifestations of ICH are usually recognized early and include seizures, meningismus, and a tense fontanelle.

Although severe deficiency of factor VIII is the most common cause of ICH from a coagulation factor deficiency, severe congenital deficiencies of fibrinogen and factors II, V, VII, VIII, IX, X, XI, and XIII can also cause ICH at birth.[187] The incidence of ICH in newborns is unknown and is probably changing because of improvements in perinatal care. The widespread use of ultrasound, a safe modality for monitoring fetuses at risk, has resulted in the detection of ICH in utero. In utero factor replacement has been accomplished in several infants. Though less common than ICH, subgaleal bleeding with concurrent shock and DIC may be the initial manifestation of a congenital factor deficiency.[188]

Diagnosis. In newborns, the diagnosis of many congenital factor deficiencies based on plasma concentrations can be difficult because of neonates' physiologically low levels at birth (see Appendix Tables 5-2 and 5-3). Mild to moderate hereditary deficiencies of factors II, VII, IX, X, and XI result in plasma concentrations that may overlap with the normal neonatal range. In contrast, plasma concentrations resulting from either mild to moderate factor VIII deficiency or severe deficiency of factors V, VII, VIII, IX, X, and XIII can easily be distinguished from physiologic values. Prenatal diagnosis of most hereditary factor deficiencies is performed by amniocentesis or chorionic villus biopsy and is largely confined to severe hemophilia A and B, although deficiencies of factors V, VII, and XIII and VWF have also been diagnosed prenatally.[10,11,189-191]

Treatment. In the presence of active bleeding or a planned hemostatic challenge, the fundamental principle of management is to increase the plasma concentration of the deficient coagulation protein to a minimal hemostatic level. This target level varies, depending on the protein and nature of the hemostatic challenge (see Chapters 31 and 32). When possible, recombinant protein products or detergent-treated pooled donor preparations should be used to reduce the risk of infectious complications. Most products available for the treatment of older children and adults can be used in neonates. Although it has not been well studied, the half-lives and volumes of distribution of recombinant factor VIII (rFVIII) and recombinant factor IX (rFIX) appear to be similar in full-term newborns and older children, so standard initial dosing regimens can be used. However, it is critical to monitor trough levels closely and make appropriate dose modifications to ensure achievement of the proper target level. There are a few case reports of extremely premature infants (<1500 g or <30 weeks' EGA) having a slightly shortened half-life of factor VIII (about 6 hours vs. 8 to 12 hours in full-term infants and older children).[192,193]

Fresh frozen plasma (FFP) should be given for bleeding emergencies in neonates in whom a coagulation defect is suspected but a specific factor deficiency has not yet been documented. There are case reports of a small number of infants (<4 months) treated with recombinant factor VIIa (rFVIIa) for catastrophic bleeding of varying causes.[194-196] However, rFVIIa treatment of patients without congenital factor VII deficiency or hemophilia with high-titer inhibitors should be considered investigational at this time. Infants with known or suspected deficiencies in coagulation factors should receive vaccinations by the subcutaneous rather than the intramuscular route, and arterial puncture should be avoided when possible.

Mode of Delivery. The optimal mode of delivery for infants of hemophilia carrier mothers has yet to be determined.[153,184] However, normal vaginal delivery appears to be generally safe for many babies with hemophilia.[184,197] Use of vacuum assistance is associated with an increased risk for significant cranial hematomas in newborns with hemophilia and should be avoided if possible.[153,184,197]

Specific Coagulation Factor Deficiencies

Fibrinogen Deficiency. Deficiency of fibrinogen is rare. Bleeding secondary to afibrinogenemia has been reported in newborns after circumcision or as umbilical stump bleeding and soft tissue hemorrhage, with some cases being fatal. Reported replacement therapies have included whole blood, cryoprecipitate, FFP, and fibrinogen concentrates.[198-201] One fibrinogen concentrate (Haemocomplettan HS, Centeon/Aventis Behring) is available in Europe and North America.

Factor II Deficiency. Deficiency of prothrombin is very rare. Reported bleeding complications in newborns include gastrointestinal bleeding and ICH.[202,203] Reviews of adult patients have reported bleeding after invasive events such as circumcision and venipuncture or as soft tissue hematomas.[199] Although FFP can be used as initial therapy, factor II concentrate or prothrombin complex concentrate (PCC) is the preferred replacement product.

Factor V Deficiency. Bleeding as a result of severe factor V deficiency has been reported in newborns. Clinical manifestations include ICH, subdural hematoma, bleeding from the umbilical stump, gastric hemorrhage, and soft tissue hemorrhage.[204-207] Replacement therapy includes whole blood and FFP. Although thrombotic complications occur in some patients with factor V deficiency, they have not been reported in newborns.[204-208]

Factor VII Deficiency. Severe factor VII deficiency (factor VII level <1%) usually causes significant bleeding equivalent to that seen in patients with severe hemophilia. Patients with factor VII levels greater than 5% generally have mild hemorrhagic episodes. The most commonly reported bleeding complication in newborns with congenital factor VII deficiency is ICH.[209,210] In a review of 75 patients with factor VII deficiency, ICH was observed in 12 (16%). In 5 (42%) of these 12 patients, ICH occurred in the first week of life, with a fatal outcome. Congenital factor VII deficiency may occur in infants with Dubin-Johnson syndrome[210,211] or Gilbert syndrome[212] in certain populations. Bleeding episodes secondary to factor VII deficiency can be treated with FFP, PCC, purified factor VIIa concentrates, or, preferably, rFVIIa.[194,209,210,213,214] Lower doses of rFVIIa (15 to 20 μg/kg) than those used for patients with severe hemophilia and high-titer inhibitors (90 μg/kg) are often sufficient to control bleeding in patients with factor VII deficiency.[215,216] However, this has not been carefully defined in prospective clinical trials. Moreover, dosing has not been optimized for neonates and infants. Caution should be used in combining treatment with rFVIIa and PPC because thrombotic complications have been reported.

Factor VIII Deficiency. The severity of factor VIII deficiency is determined by the plasma concentration of factor VIII, with a level of less than 1% being severe, 1% to 5% being moderate, and 5% to 50% being mild. Severe factor VIII deficiency is the most common inherited bleeding disorder of the neonatal period. In addition, a small number of neonates with moderate and mild hemophilia are seen after a hemostatic challenge.[156,158,217-219] Large cohort studies have revealed that approximately 10% of children with hemophilia have clinical symptoms in the neonatal period.[187] In this group of factor VIII–deficient children experiencing bleeding in the neonatal period, approximately 50% of bleeding episodes occur after circumcision, with almost 20% of patients suffering intracranial bleeding; some deaths also occur. In contrast to older infants and children, bleeding into joints is extremely rare in neonates.[220] Severe factor VIII deficiency can, on rare occasion, occur in female infants as a result of homozygosity or compound heterozygosity for an FVIII gene mutation[221] or skewed lyonization.[222,223] Management of bleeding secondary to factor VIII deficiency is discussed in detail in Chapter 31.

Factor IX Deficiency. Classification of the severity of factor IX deficiency is identical to that used for factor VIII deficiency. Diagnosis of milder forms of factor IX deficiency is complicated by physiologic levels of factor IX that can be as low as 0.15 U/mL and, in rare infants, by the potential for concurrent VK deficiency. Bleeding after circumcision and ICH can occur in neonates with factor IX deficiency.[156,158,217,224,225] Management of bleeding secondary to factor IX deficiency is discussed in detail in Chapter 31.

Factor X Deficiency. Severe factor X deficiency can be manifested as bleeding in the newborn period.[226-230] ICH was present in a high proportion of reported cases, several of which were fatal. Additional sites of bleeding that have been noted include umbilical, gastrointestinal, and intraabdominal sites. Whole blood, FFP, factor X concentrate, and PCC have been used as replacement therapy.

Factor XI Deficiency. Severe deficiency of factor XI is rare. It is different from other coagulation protein deficiencies in that bleeding symptoms are not necessarily tightly correlated with factor plasma concentrations. Bleeding complications as a result of severe factor XI deficiency were reported in two newborns. One bled after circumcision at the age of 3 days and had a factor XI level of 0.07 U/mL. In another newborn, factor XI deficiency with bilateral subdural hemorrhage was diagnosed prenatally.[231-233] Either FFP or cryoprecipitate can be used for the treatment of factor XI–deficient patients if factor XI concentrate is not available.

Factor XIII Deficiency. Severe factor XIII deficiency is typically manifested at birth as bleeding from the umbilical stump or ICH.[157,234-243] Other clinical manifestations of homozygous factor XIII deficiency include delayed wound healing, abnormal scar formation, and recurrent soft tissue hemorrhage with a tendency to form hemorrhagic cysts. ICH occurs even in the absence of trauma in approximately a third of all affected patients.[153] Newborns with heterozygous factor XIII deficiency are not clinically affected.

FFP, cryoprecipitate, or factor XIII concentrates can be used for the treatment of factor XIII–deficient patients. Newborns with known factor XIII deficiency should receive a prophylactic regimen of factor XIII because of the high incidence of ICH. Plasma concentrations of factor XIII greater than 1% are effective, and the very long half-life of factor XIII permits once-per-month therapy. Therefore prophylactic replacement therapy consists of either small doses of FFP (2 to 3 mL/kg) administered every 4 to 6 weeks, cryoprecipitate at a dose of 1 bag/10 to 20 kg of weight every 3 to 6 weeks, or, preferably, factor XIII concentrate at a dose of 10 to 20 U/kg every 4 to 6 weeks, depending on the clinical situation and the preinfusion plasma concentration of factor XIII.[157,234-245]

Hereditary Deficiencies of Multiple Coagulation Factors. Hereditary deficiencies of two or more coagulation proteins have been reported for 16 different combinations of coagulation factors.[172,246,247] Combined deficiency of factors V and VIII has been described in patients with mutations in the genes encoding LMAN1 (also called ERGIC-53) and MCFD2.[174,248] Administration of FFP is usually the initial therapy. Subsequent treatment varies, depending on the specific factors affected.

Hemorrhagic Disease of the Newborn

Historical Background. HDN, as first described by Townsend in 1894, consists of hemorrhage on days 1 through 5 of life from multiple sites in otherwise healthy infants.[249] Subsequently, a causal link between HDN and abnormal blood coagulation was established.[72,250,251] Initial treatment of infants with HDN consisted of intravenous, intramuscular, or subcutaneous injection of blood or serum. Even at this very early time, the difficulty of separating treatment response from spontaneous improvement was recognized. Later, a randomized, controlled trial showed that intramuscular injection of blood was not helpful in preventing the abnormalities in blood coagulation that occurred during the first week of life.[250] The link between VK deficiency and spontaneous hemorrhage was first recognized in chicks in 1929.[252] The association between VK deficiency and HDN quickly followed, as subsequently did treatment of infants with HDN.[72,253-255]

The next historical step was recognition of the link between decreased prothrombin activity and increased PT on days 2 to 4 of life in the absence of prophylactic VK. Prothrombin activity was observed to return to normal by days 5 to 7 of life.[72,256-259] These observations led to the hypothesis that VK administered prophylactically could prevent HDN.[256,257,260-262] There was uniform agreement that the prophylactic administration of VK to mothers or infants prevented the decrease in prothrombin activity during the first 3 to 4 days of life.[72,255,256] On the basis of these studies, VK prophylaxis was widely recommended. Subsequently, the scientific basis for this policy became less clear for several reasons. First, plasma concentrations of other coagulation proteins in addition to prothrombin were shown to be low in newborns. Second, there was increasing recognition that bleeding in neonates was often not due to VK deficiency.[72,251,263-265] Third, administration of high amounts (50 to 70 mg) of a water-soluble form of VK resulted in hemolytic anemia with kernicterus in some infants.[72,266,267] Fourth, many clinicians suggested that VK prophylaxis was not needed for all healthy full-term infants.[265,268-270] Consequently, VK prophylaxis was suspended in some countries, and recurrence of HDN ensued.[72,257,271-282] Most of the controversy concerning prophylactic use of VK can be explained by the design of the trials and subsequent interpretation of their results. The best evidence comes from large randomized, placebo-controlled trials. Such trials have consistently shown a statistically significant benefit from VK prophylaxis in terms of clinical bleeding.[283-285] No randomized, controlled trials with large enough sample size have shown that prophylactic VK does not prevent bleeding.

Prophylactic Vitamin K Administration. VK exists in three forms: VK_1 (phytonadione), which is present in leafy green vegetables; VK_2 (menaquinone), which is synthesized by intestinal bacterial flora; and VK_3 (menadione), which is a synthetic, water-soluble form. VK_3 is rarely used in newborns because at high doses it causes hemolytic anemia, which results in jaundice and potential morbidity.[72,266,267] The recommendations for VK prophylaxis in many countries are similar.[55] Daily requirements of VK are approximately 1 to 5 μg/kg of body weight for newborns.[55] Most groups recommend a single dose of 0.5 to 1 mg intramuscularly or an oral dose of 2 to 4 mg at birth, with subsequent dosing for breastfed infants. Oral VK prophylaxis is preferable to parenteral prophylaxis; studies have shown that oral administration of VK is as effective, less expensive, and less traumatic than intramuscular administration in preventing the classic signs and symptoms of VK deficiency.[55] However, orally administered VK_1 or VK_3 may not be as effective as intramuscularly injected VK in the prevention of late VK deficiency.[286] Strategies for preventing late VK deficiency include repeat administration of oral VK[281,287] or continuous low-dose VK supplementation.[281] A mixed micelle oral VK_1 preparation that is readily absorbed has been tested in children.[55] However, optimal dosing of this preparation to prevent late VK deficiency bleeding remains to be determined.[288]

In addition to general prophylaxis at birth, patients in certain risk groups require additional VK prophylaxis (e.g., infants with α_1-antitrypsin deficiency, chronic diarrhea, cystic fibrosis, or celiac disease). Pregnant women receiving oral anticonvulsant therapy should take 10 mg of oral VK_1 daily beginning at 36 weeks' gestation for the prevention of overt VK deficiency in their infants at birth.[69]

In 1990, a cohort study aimed at determining perinatal risk factors for childhood cancer reported an association between drugs administered in the peripartum period (maternal pethidine or neonatal VK) and childhood cancer (odds ratio, 2.6).[289] A subsequent case-control study by the same group found no association between maternal pethidine and childhood cancer; however, they again reported an increased risk of childhood cancer after neonatal intramuscular VK administration (odds ratio, 1.97).[290] In contrast, a later large case-control study of 2530 children with cancer, one ecologic study, and one metaanalysis have shown no association between VK administration and childhood cancer.[291,292] The current consensus of the American Academy of Pediatrics Committee on Fetus and Newborn is that the risk for increased childhood cancer is probably minimal, if any, and the benefits of VK prophylaxis in terms of reduced bleeding are substantial.[293]

Bleeding Caused by Vitamin K Deficiency in the Newborn. In the absence of prophylactic VK, the incidence of vitamin K–dependent bleeding (VKDB) ranges from 0.25% to 1.7%.[72,283] Infants are at greater risk for hemorrhagic complications from VK deficiency than similarly affected adults are because their plasma concentrations of VK-dependent factors are physiologically

TABLE 5-1 Forms of Bleeding Resulting from Vitamin K Deficiency in Infancy

Parameter	Early Form	Classic Form	Late Form
Age	<24 hours	2-7 days	0.5-6 months
Causes and risk factors	Medications during pregnancy Anticonvulsants Oral anticoagulants (rifampin, isoniazid) Antibiotics (rarely, idiopathic or hereditary)	Breastfeeding Inadequate VK intake	Marginal VK content in breastmilk resulting from low VK intake and absorption Cystic fibrosis Diarrhea α_1-Antitrypsin deficiency Hepatitis Celiac disease
Localization in order of occurrence	ICH Gastrointestinal region Umbilicus Intraabdominal region Cephalhematoma	ICH Gastrointestinal region Umbilicus ENT region Injection sites Circumcision	ICH (>50%) Gastrointestinal region Skin ENT region Injection sites Urogenital tract Intrathoracic region
Occurrence without VK prophylaxis	Very rare	1.5% (1/10,000 births)	4-10/10,000 births*
Prophylaxis	Discontinue or replace offending medications Maternal VK prophylaxis	Adequate VK supply Early and adequate breastfeeding Formula VK prophylaxis	Adequate VK supply Adequate breastfeeding Formula VK prophylaxis†

ENT, Ear, nose, and throat region; *VK*, vitamin K.
*More common in Southeast Asia.
†A single intramuscular injection is better than a single oral dose; repeated small doses are closer to physiologic conditions.

decreased.[18,21,26,72,282,294] The clinical manifestation of VKDB can be classified as classic, early, or late on the basis of the timing and type of complications (Table 5-1). Classic VKDB initially occurs on days 2 to 7 of life in breastfed, healthy full-term infants.[64,72,277,294-297] Causes include poor placental transfer of VK,[54,56-58] marginal VK content in breastmilk (<20 mg/L), inadequate milk intake, and a sterile gut.[72] VKDB rarely occurs in formula-fed infants because commercially available formulas are supplemented with VK.[298,299] How often classic VKDB occurs in the absence of VK prophylaxis depends on the population studied, the supplemental formula, and the number of mothers breastfeeding. Early VKDB develops in the first 24 hours of life and is linked to maternal use of specific medications that interfere with VK stores or function, such as some anticonvulsants.[300-302] Late VKDB occurs between weeks 2 and 8 of life and is linked to disorders that compromise ongoing VK supply.[303,304]

Laboratory Diagnosis of Vitamin K Deficiency in the Newborn. Laboratory tests used to detect VK deficiency include screening coagulation tests, specific factor assays, measurement of decarboxylated forms of VK-dependent factors, PIVKA (protein induced by VK antagonists) assays, and direct measurements of VK levels. The results of these tests must always be compared with values for age-matched, healthy, non–VK-deficient infants to distinguish physiologic and pathologic deficiencies.[65,305]

Treatment. An infant suspected of having VK deficiency should be treated immediately with VK while laboratory confirmation is awaited. All infants with VKDB should be given VK either subcutaneously or intravenously, depending on the clinical problem. VK should not be given intramuscularly to infants with VKDB, because large hematomas may form at the site of the injection. Absorption of subcutaneously administered VK is rapid, and its effect occurs only slightly slower than that of systemically administered VK. Intravenous VK should be given slowly and with a test dose because it may induce an anaphylactoid reaction. Infants with major bleeding because of VK deficiency should also be treated with plasma products to rapidly increase levels of VK-dependent proteins. Plasma is the product of choice for treatment of a non–life-threatening hemorrhagic event, whereas PCCs should be considered for the management of life-threatening bleeding.

Liver Disease

The coagulopathies associated with liver disease in newborns are similar to those of adults and reflect the failure of hepatic synthetic function. However, in newborns this problem may be superimposed on the already “physiologic” immaturity of the coagulation system, activation of the coagulation and fibrinolytic systems, poor clearance of activated coagulation factors, and loss of hemostatic proteins into ascitic fluid.[306] Secondary effects of liver disease on platelet number and function also occur in newborns.[307,308] Common causes of hepatic dysfunction in newborns include viral hepatitis, hypoxia, total parenteral nutrition, shock, and fetal hydrops. Rare causes include genetic diseases such as α_1-antitrypsin deficiency, galactosemia, and tyrosinemia.

Laboratory abnormalities induced by acute liver disease include prolongation of the PT and low plasma concentrations of several coagulation proteins, including fibrinogen.[309,310] However, it is important to compare these levels with those of normal age-matched controls (see Appendix Tables A5-1 to A5-3). Fibrinogen is present at adult levels in newborns and may be a useful marker. Chronic liver failure with cirrhosis is also characterized by a coagulopathy and mild thrombocytopenia.[311-314] Secondary VK deficiency may occur as a result of impaired absorption from the small intestine, particularly in those with intrahepatic and extrahepatic biliary atresia.[315] Patients with clinical bleeding may benefit temporarily from replacement of coagulation proteins with FFP, cryoprecipitate, or exchange transfusion. However, without recovery of hepatic function, replacement therapy is futile. VK should be administered to infants in whom cholestatic liver disease is suspected.

von Willebrand Disease

Although von Willebrand disease (VWD) is the most common inherited bleeding disorder, patients with the disease rarely present in the neonatal period. Plasma concentrations of VWF are increased in neonates, as is the proportion of ULVWF multimers.[83,84] Nonetheless, severe deficiency (type 3) and some qualitative VWF disorders (type 2) have been reported to present in the newborn period.[316-319] Management of VWD is discussed in detail in Chapter 31. Use of arginine vasopressin in the newborn period is contraindicated because of associated excess free water retention.

Platelet Disorders

Quantitative Platelet Disorders. The definition of thrombocytopenia in newborns is the same as that in adults: a platelet count less than $150 \times 10^9/L$. Consequently, platelet counts less than $150 \times 10^9/L$ are abnormal and indicate the need for investigation and, sometimes, treatment. Mean platelet volumes in newborns are similar to those of adults (range, 7 to 9 fL).[96-98] Postnatally, the mean platelet volume increases slightly over the first 2 weeks of life, concomitantly with an increase in platelet count.[99,100]

Epidemiology. Thrombocytopenia is the most common hemostatic abnormality in newborns admitted to neonatal intensive care units (NICUs).[93,95,97,98,320] A single prospective cohort study[97] and six retrospective reviews[98,321-325] have provided the most reliable information on the occurrence, natural history, mechanisms, and clinical impact of thrombocytopenia in newborns. There is general agreement that thrombocytopenia indicates the presence of an underlying pathologic process; however, the clinical relevance of mild thrombocytopenia is unknown. Thrombocytopenia develops in approximately 22% to 35% of infants and approximately 75% of extremely low birth weight neonates admitted to the NICUs of tertiary hospitals.[97,326,327] In some infants the thrombocytopenia is trivial, with platelet counts between 100 and 150 $\times 10^9/L$. However, in 50% of affected infants, platelet counts decrease to less than $100 \times 10^9/L$, and in 20% of infants, platelet counts are lower than 50 $\times 10^9/L$. What constitutes a safe platelet count in a neonate remains to be rigorously determined,[327-329] but many neonatal units attempt to keep the platelet count higher than $50 \times 10^9/L$, although this figure may vary, depending on the postconceptional age of the infant and comorbid conditions.

Pathogenesis. Causes of thrombocytopenia in neonates, like those in older children and adults, can be divided into disorders involving increased platelet destruction, decreased platelet production, or sequestration (Box 5-1). Although many of these causes overlap with those seen in older children and adults, several entities are unique to neonates or may occur in the newborn period and are considered in more detail here. Increased platelet destruction is the mechanism responsible for thrombocytopenia in most infants.[97,330] Characterization of mechanisms responsible for thrombocytopenia is important because they have practical implications in assessing the risk for bleeding and in guiding management.

Increased Platelet Destruction. Thrombocytopenia secondary to increased platelet destruction can be divided into immune and nonimmune causes.

Immune Thrombocytopenia. Immune thrombocytopenia is defined as an increased rate of platelet clearance caused by platelet-associated immunoglobulin G (IgG) or complement. It is the most common form of increased platelet destruction in newborns and should always be suspected in otherwise healthy infants with isolated severe thrombocytopenia. Neonatal immune thrombocytopenia can be further broken down into one of three processes: transplacental passage of a maternal antibody directed against a nonshared platelet antigen (termed alloimmune thrombocytopenia or, sometimes, isoimmune thrombocytopenia), transplacental passage of a cross-reactive maternal autoimmune-derived antiplatelet antibody, or generation of an autoreactive antiplatelet antibody by the newborn itself (termed autoimmune thrombocytopenia). The second can be distinguished from the other two by examining the mother for a low platelet count. Differentiation of autoimmune thrombocytopenia from alloimmune thrombocytopenia in neonates is critical because the management and severity of these disorders are quite different. Chapter 34 discusses these two forms of immune thrombocytopenia and their management in detail.

Neonatal Alloimmune Thrombocytopenia. Neonatal alloimmune thrombocytopenia (NAIT) is the most common cause of immune-mediated thrombocytopenia in the newborn period, with an estimated incidence of about 1 in 1000 to 5000 live births in white populations.[331-335] It arises when the mother, who lacks a common platelet antigen, is exposed to the antigen (inherited from the father) on neonatal platelets and generates a neutralizing IgG. This crosses the placenta and mediates premature clearance of fetal and newborn platelets. First-born infants can be affected. Frequently, the thrombocytopenia is severe. It is critical to make the diagnosis because the risk of life-threatening bleeding and central nervous system morbidity is high, estimated at up to 10% to 15% of cases. A useful diagnostic test is to assay the reactivity of the mother's serum with the father's platelets. If such samples are not available, it is possible to look for reaction of the mother's serum with the newborn's platelets or the presence of antiplatelet antibodies in the newborn's serum. The most common antigen is HPA-1a (formerly called Pl^{A1}), although other antigens, such as HPA-3a

Box 5-1 Causes of Thrombocytopenia in Newborns

- INCREASED DESTRUCTION OF PLATELETS
  - Immune-mediated destruction
    - Neonatal alloimmune thrombocytopenia
    - Maternal idiopathic thrombocytopenic purpura
    - Drug-dependent antibody (could be from maternal medication use)
    - Autoimmune thrombocytopenic purpura
  - Non–immune-mediated destruction
    - Pseudothrombocytopenia (platelet clumping) in vitro
    - Disseminated intravascular coagulation
    - Asphyxia and placental insufficiency
    - Perinatal aspiration
    - Necrotizing enterocolitis
    - Hemangiomas (Kasabach-Merritt syndrome)
    - Thrombosis (may be occult)
    - Respiratory distress syndrome
    - Maternal preeclampsia
    - Cardiopulmonary bypass (including extracorporeal membrane oxygenation [ECMO])
    - Familial thrombotic thrombocytopenic purpura
  - Other syndromes of destruction
    - Hyperbilirubinemia
    - Phototherapy
    - Polycythemia
    - Rh hemolytic disease
    - Total parenteral nutrition
- DECREASED PRODUCTION OF PLATELETS
  - Acquired disorders
    - Viral infection (e.g., human immunodeficiency virus, cytomegalovirus, rubella virus, human herpesvirus 6)
    - Congenital leukemia
    - Down syndrome–transient myeloproliferative disorder (DS-TMD)
    - Neuroblastoma
    - Histiocytosis
    - Osteopetrosis
  - Inherited disorders
    - *Disorders associated with small platelets*
      - Wiskott-Aldrich syndrome (WAS)
      - X-linked thrombocytopenia (associated with Wiskott-Aldrich syndrome protein [WASP])
    - *Disorders associated with normal-size platelets*
      - Thrombocyopenia with absent radii (TAR)
      - Amegakaryocytic thrombocytopenia with radioulnar synostosis (ALTRUS)
      - Congenital amegakaryocytic thrombocytopenia (CAMT)
      - Familial platelet disorder with propensity for development of acute myelogenous leukemia (FPD/AML)
      - ANKRD26-related thromobocytopenia (THC2)
      - Cytochrome C–related thrombocytopenia (CYCS)
    - *Disorders associated with large platelets*
      - X-linked macrothrombocytopenia with or without anemia (*GATA-1* mutations)
      - MYH9-related disorders (May-Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, Epstein syndrome)
      - Bernard-Soulier syndrome
      - Paris-Trousseau/Jacobsen syndrome
      - Velocardiofacial syndrome
      - Montreal platelet syndrome
      - Gray platelet syndrome
      - Platelet-type von Willebrand diseaes (pseudo–von Willebrand disease)
      - Filamin-related thrombocytopenia
      - Tubulin-related thrombocytopenia
      - Thrombocytopenia associated with sitosterolemia
    - *Other disorders*
      - Fanconi anemia
      - Metabolic disorders (e.g., methylmalonic acidemia, ketotic glycinemia, isovaleric acidemia)
      - Drug-mediated suppression
- SEQUESTRATION
  - Hypersplenism

(formerly called Bak^{a}), HPA-4a (formerly called Pen^{a} [more common in Asian populations]), HPA-5a (formerly called Br^{b}), and HPA-5b (formerly called Br^{a}), have been described.[336] Not all cases in which the pregnant mother generates allosensitive antiplatelet antibodies result in neonatal thrombocytopenia.

Treatment of NAIT includes transfusion with washed platelets donated by the mother. Because the mother's platelets lack the offending antigen, they should have a normal life span. Many blood banks also maintain registries of HPA-1a–negative donors who can be contacted for platelet donation in cases involving antibodies against HPA-1a. If antigen-negative platelets are not available, treatment with intravenous immunoglobulin, 1 g/kg as a single daily bolus for 1 or 2 consecutive days, along with random donor platelets if the patient is bleeding, is effective in reducing the rate of platelet destruction.[337-340] Endogenous platelet counts typically rise by 36 to 48 hours. The role of corticosteroids in the treatment of infants with NAIT is unclear, and they are typically not used as initial therapy. All infants with NAIT should undergo head ultrasonography or computed tomography to rule out ICH. The natural history of NAIT is gradual resolution of the thrombocytopenia over the first few months of life as the offending antibody is cleared. Close monitoring of the platelet count is indicated for at least the first month of life until the platelet count normalizes. The safety of breastfeeding in the setting of NAIT has not been rigorously studied. One case report suggested that breastfeeding did not significantly worsen the clinical course, even though the breastmilk contained antiplatelet IgG.[341]

Immune Thrombocytopenia Caused by Maternal Antiplatelet Autoantibodies. Maternal autoimmune antiplatelet IgG can cross the placenta and result in increased platelet destruction in the fetus. A common cause is maternal systemic lupus erythematosus. Like NAIT, the thrombocytopenia gradually resolves over the first few months of life as the maternal antibodies are cleared. In severe cases, use of intravenous immunoglobulin in the neonate may help reduce the rate of platelet destruction. Corticosteroids are of no clear utility. Drug-dependent antibodies can result in both maternal and neonatal thrombocytopenia.[125]

Autoimmune Thrombocytopenia. True autoimmune thrombocytopenia, in which neonates generate an antibody against their own platelets, is very rare in the newborn period. If present, it typically signals an underlying immune dysregulatory disorder. If heparin-induced thrombocytopenia is suspected, heparin therapy should be discontinued immediately and alternative forms of anticoagulation considered if necessary (see Chapter 34).

Nonimmune Thrombocytopenia

Sepsis and Disseminated Intravascular Coagulation. A common nonimmune cause of thrombocytopenia in the newborn period is sepsis, with or without DIC. Viral infections (rubella virus, herpesvirus, echovirus, cytomegalovirus, human herpesvirus 6, and human immunodeficiency virus), protozoal infections (Toxoplasma), and bacterial infections cause severe thrombocytopenia.[342] Mechanisms responsible for bacterial sepsis–induced thrombocytopenia are multifactorial and include consumption resulting from DIC, endothelial damage, platelet aggregation caused by binding of bacterial products to platelet membranes, and decreased production as a result of marrow infection.[343] Mechanisms responsible for virus-induced thrombocytopenia include loss of sialic acid from platelet membranes because of viral neuraminidase, intravascular platelet aggregation, and impaired megakaryopoiesis (see later). Congenital rubella causes thrombocytopenia in three quarters of infants, with platelet counts ranging from 20 to 60 × 10^9/L for the first 4 to 8 weeks of life.

In premature infants, thrombocytopenia often complicates other disorders such as RDS, persistent pulmonary hypertension, necrotizing enterocolitis, and hyperbilirubinemia treated by phototherapy. Activation of coagulation with platelet consumption occurs in RDS, and mechanical ventilation may be an independent factor contributing to thrombocytopenia.[344] It has been suggested that persistent pulmonary hypertension in newborns may be due in part to intrapulmonary platelet aggregation and the release of platelet-derived vasoactive substances such as thromboxane A_2.[345] Approximately half of infants with necrotizing enterocolitis are thrombocytopenic, with about 20% having laboratory evidence of DIC.

Exchange Transfusion, Hyperbilirubinemia, and Phototherapy. Intrauterine and exchange transfusions cause thrombocytopenia by a dilutional effect that depends on the amount of blood transfused.[322] After exchange transfusion, platelet counts increase within 3 days and reach preexchange levels by about 7 days.[43] Both hyperbilirubinemia and phototherapy are associated with mild thrombocytopenia in newborn humans and shortened platelet survival in rabbits.[330]

Hypoxia and Placental Insufficiency. Acute asphyxia is a consistent cause of DIC and thrombocytopenia.[103] Chronic hypoxia is associated with placental dysfunction, intrauterine growth retardation, and significant thrombocytopenia.

Vascular Malformations. Certain types of large vascular malformations are associated with Kasabach-Merritt syndrome, in which a local consumptive coagulopathy occurs as a result of abnormal endothelium. This causes hypofibrinogenemia, elevated levels of fibrinogen-fibrin degradation products, microangiopathic fragmentation of red cells, and thrombocytopenia (see Chapter 34).[346-350] The thrombocytopenia can be severe, with platelet counts lower than 50 × 10^9/L. Approximately 50% of affected infants experience systemic bleeding during the first month of life. Sometimes the vascular malformations are not apparent on physical examination and require imaging studies to detect.

Thrombosis and Familial Thrombotic Thrombocytopenic Purpura. Thrombocytopenia is loosely associated with thromboembolic complications and polycythemia in infants with hematocrit values greater than 70%. However, thrombocytopenia may also indicate the presence of other concurrent disease processes. Infants with a familial form of hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura have a microangiopathic hemolytic anemia in association with transient neurologic or renal abnormalities (see Chapter 34).

Decreased Platelet Production. Thrombocytopenia secondary to decreased platelet production is rare and accounts for less than 5% of thrombocytopenic infants.[43,93-95] Causes include viral infections, drug-induced thrombocytopenia, congenital leukemia, Down syndrome transient myeloproliferative disorder (DS-TMD), neuroblastoma, histiocytosis, osteopetrosis, congenital amegakaryocytic thrombocytopenia (CAMT), thrombocytopenia with absent radius syndrome (TAR), other inherited genetic platelet disorders, and bone marrow failure syndromes.

CONGENITAL VIRAL INFECTION. Congenital viral infections with rubella virus, herpesvirus, echovirus, cytomegalovirus, human herpesvirus 6, and human immunodeficiency virus have been associated with thrombocytopenia in the newborn period, in part through deleterious effects on megakaryopoiesis and thrombopoiesis.

DRUG-INDUCED THROMBOCYTOPENIA. Transplacental passage of drugs or the use of drugs in neonates can cause thrombocytopenia via bone marrow suppression or the development of drug-dependent antibodies, or both.[125] However, these causes are rare, and evidence for them is weak.[351-354] Agents implicated are salicylates, quinine, hydralazine, tolbutamide, and thiazide diuretics.

CONGENITAL LEUKEMIA AND OTHER MALIGNANT DISEASES. Infantile leukemia, as well as other neonatal malignant diseases characterized by bone marrow infiltration, such as neuroblastoma, can be accompanied by thrombocytopenia in the newborn period. Typically, other hematopoietic lineages are affected and other clinical signs are apparent. An infantile form of myelofibrosis has been described in several families in Saudi Arabia.[355,356]

DOWN SYNDROME–TRANSIENT MYELOPROLIFERATIVE DISORDER. Some infants with Down syndrome (DS) (trisomy 21) are born with a transient myeloproliferative disorder (DS-TMD) characterized by leukocytosis, thrombocytopenia, predominance of circulating early erythromegakaryocytic precursor cells, pancytopenia, and, in some cases, severe liver fibrosis.[357] Remarkably, this myeloproliferation resolves spontaneously over the first few months of life. In about 20 % of symptomatic cases, acute megakaryocytic leukemia (DS-AMKL) develops within a few years.[358] The DS-TMD and DS-AMKL cells harbor acquired mutations in the gene encoding the erythromegakaryocytic transcription factor GATA-1.

Inherited Platelet Disorders. Though considerably less common than consumptive processes or viral suppression, inherited platelet disorders can occur in the newborn period and should be considered in the differential diagnosis of thrombocytopenia in a neonate. They are discussed in more detail in Chapter 30 (also see Box 5-1 for a complete listing). Several classifications, diagnostic algorithms, and management recommendations have been published.[359,360] Infants with aplastic disorders have the greatest risk of serious bleeding in the form of ICH in the first months of life. Brief descriptions of selected syndromic disorders with specific neonatal manifestations are given here.

Disorders with Small Platelets

WISKOTT-ALDRICH SYNDROME. Wiskott-Aldrich syndrome (WAS; OMIM 301000) is an X-linked disorder caused by deficiency of the Wiskott-Aldrich syndrome protein, which functions in actin dynamics in megakaryocytes and T lymphocytes. It is one of the few disorders characterized by small platelets. The small size of the platelets is not always apparent by standard automated measurements of blood cell mean platelet volume. Therefore if the diagnosis is being considered, it is imperative to evaluate platelet size by examination of the peripheral smear and to confirm small platelet volume with cytometer devices calibrated for platelets. The other clinical hallmarks of WAS are immunodeficiency (usually severe) and eczema. Bloody diarrhea is often seen and can be an initial sign. The immunodeficiency is frequently the most significant clinical problem associated with this disease. It is important to recognize the syndrome early so that appropriate interventions can be instituted, including prophylactic treatment against opportunistic infections such as Pneumocystis carinii infection. A destructive component of the thrombocytopenia in WAS is also likely because splenectomy increases platelet counts in a large number of patients. In addition, the thrombocytopenia can be exacerbated by development of immune thrombocytopenic purpura secondary to the immune dysregulation. Bone marrow transplantation is curative for WAS, and early diagnosis is helpful in initiating listing for transplantation before significant complications arise.

X-LINKED THROMBOCYTOPENIA. X-linked thrombocytopenia (OMIM 313900) is a less severe form of WAS that is manifested predominantly as thrombocytopenia. Typically, there is no or minimal immunologic dysfunction. However, more severe immunologic disturbances may develop in some patients over time. This clinical entity is distinct from X-linked macrothrombocytopenia, which is associated with germline mutations in GATA-1.

Disorders with Normal-Size Platelets

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA. Congenital amegakaryocytic thrombocytopenia (CAMT; OMIM 604498) is characterized by severe thrombocytopenia with a markedly reduced number or absence of megakaryocytes. Patients are typically seen shortly after birth with petechiae, bruising, or bleeding. Biallelic inactivating mutations in the gene for c-mpl, the receptor for the major megakaryocyte cytokine TPO, have been identified in a large number of patients. Interestingly, no patients have been reported to date with mutations in the TPO gene itself. Patients with severe CAMT are at high risk for the development of complete bone marrow failure, usually within the first few years of life.[361] Such failure is most likely due to a role of TPO signaling in hematopoietic stem cell function.[362,363] Bone marrow transplantation has been used successfully to treat patients with severe CAMT.

THROMBOCYTOPENIA WITH ABSENT RADII. Thrombocytopenia with absent radii syndrome (TAR; OMIM 274000) is characterized by hypomegakaryocytic thrombocytopenia and bilateral radial hypoplasia with the presence of thumbs.[364] Other hematopoietic lineages are not affected. Additional skeletal features may include shortening or, rarely, aplasia of the humerus and ulna. The lower limbs are frequently affected but to a lesser extent. Congenital cardiac disease and cow's milk intolerance have also been associated in some cases. The genetic basis of TAR has recently been clarified.[365-367] Common interstitial microdeletions of 200 kb on chromosome 1q21.1 have been detected in several families with TAR, and the key gene within this region is thought to be RBM8A, which encodes a subunit of the exon junction complex involved in RNA processing. Microdeletion or monoallelic null mutations in RBM8A are typically insufficient to cause disease. However, coinheritance of a low-frequency single-nucleotide polymorphism in an RBM8A gene regulatory sequence on the opposite allele is associated with disease penetrance.

Neither splenectomy nor steroids are beneficial for infants with TAR.[368,369] Platelet transfusions are highly effective but should be reserved for symptomatic infants because prophylactic platelet transfusions could result in refractoriness as a result of allosensitization.[369] By several months of age, increased numbers of megakaryocytes usually appear in the bone marrow, and platelet counts increase.[368,369] A functional platelet defect may be present in some children with TAR.[370]

AMEGAKARYOCYTIC THROMBOCYTOPENIA WITH RADIOULNAR SYNOSTOSIS. Amegakaryocytic thrombocytopenia with radioulnar synostosis (ATRUS; OMIM 605432) is a rare disorder characterized by reduced or absent megakaryocytes, severe thrombocytopenia, possible aplastic anemia, and proximal radioulnar synostosis leading to difficulty with forearm pronation. Sensorineural hearing loss may also be present. Mutations in the gene encoding the homeobox containing transcription factor HOXA11 have been found in some familial cases of ATRUS.[371,372]

Disorders with Large Platelets

PARIS-TROUSSEAU SYNDROME OR JACOBSEN SYNDROME. Paris-Trousseau syndrome (OMIM 188925) (also called Jacobsen syndrome; OMIM 147791) is a constitutional contiguous gene deletion disorder involving the long arm of chromosome 11 (11q23).[373,374] The constellation of findings in this syndrome includes severe congenital cardiac abnormalities, trigonocephaly, mental retardation, dysmorphogenesis of the hands and face, and macrothrombocytopenia.[375] The cause of the thrombocytopenia appears to be related to impaired platelet production because platelet survival time is normal.[376] These patients can also exhibit a predisposition to thrombosis, thus suggesting possible qualitative defects in platelet production. Examination of bone marrow reveals significant dysmegakaryopoiesis with an abundance of micromegakaryocytes and death of large numbers of megakaryocytes during the late stages of maturation.[377] Peripheral blood platelets contain giant alpha granules, which are thought to arise from aberrant alpha-granule fusion during prolonged residence in bone marrow.[378] The minimal chromosome regions deleted in Paris-Trousseau or Jacobsen syndrome associated with thrombocytopenia include genes for the Ets family transcription factors FLI-1 and ETS-1, both of which play roles in megakaryocyte development.[379] Lentiviral expression of FLI-1 in CD34+ cells from patients with Paris-Trousseau thrombocytopenia rescues megakaryocyte differentiation in vitro, thereby providing evidence that FLI-1 deficiency is the cause of impaired thrombopoiesis in these patients.[380]

VELOCARDIOFACIAL SYNDROME. Velocardiofacial syndrome (OMIM 192430) is a contiguous gene deletion disorder involving chromosome 22q11.2. Clinical manifestations include cleft palate, cardiac anomalies, typical facies, learning disabilities, and defective GPIb/IX/V function. The platelet effects are due to heterozygous loss of the GPIbβ gene, which resides in this region, and the condition should be considered a mild form of Bernard-Soulier disorder.[381-384]

HYPERSPLENISM. As in adults, thrombocytopenia resulting from hypersplenism is usually mild to moderate, with platelet counts ranging from 50 to 100 × 10^9/L in newborns.

Clinical Impact of Neonatal Thrombocytopenia. Clinically important bleeding is less likely to occur in patients with consumptive platelet disorders than in those with production defects. The bleeding risk is increased in patients who have both thrombocytopenia and a defect in platelet function. Selection of a platelet count at which one should intervene, though a simplistic response, provides a guideline for therapy. A platelet count less than 50 × 10^9/L places some otherwise healthy full-term newborns at risk for serious ICH.[385] The importance of "moderate" thrombocytopenia (platelet counts between 50 and 100 × 10^9/L) in sick premature infants has been a subject of controversy. A randomized, controlled trial assessed the potential benefits of platelet concentrate transfusions in 154 premature thrombocytopenic infants during the first 72 hours of life.[386] Treated infants received platelet concentrates to maintain platelet counts higher than 150 × 10^9/L. No beneficial effect on the incidence or extension of ICH was shown in this study, which was designed to detect an effect of 25% or greater. However, infants who received transfusions had shortened bleeding times and required significantly less blood product support. A retrospective study of 53 neonates with severe thrombocytopenia treated at a single NICU showed no significant difference in major hemorrhage in those transfused to maintain a platelet count greater than 30 × 10^9/L versus greater than 50 × 10^9/L.[325]

Treatment. Management of thrombocytopenic infants depends in part on the underlying disorder. If an infant is bleeding, a trial of platelet concentrates (10 to 20 mL/kg) is indicated. The increased platelet count usually shortens the bleeding time and is frequently clinically effective.[132] Autoimmune and alloimmune thrombocytopenia typically does not respond to random donor platelet concentrates and requires additional specific forms of therapy.

Thrombocytosis in the Newborn. Elevated platelet counts are frequently observed in premature infants at approximately 4 to 6 weeks after birth.[387] There are no clinical manifestations of neonatal thrombocytosis, and therapeutic intervention is not indicated.

Qualitative Platelet Disorders. Despite the physiologic hyporeactivity of neonatal platelets in response to exposure to some agents, healthy infants do not have an increased risk of bleeding. Pathologic impairment of platelet function may occur, to a variable extent, as a result of the use of certain drugs or the presence of pathologic states in either mothers or infants. In mothers, causative factors include the use of some drugs, diabetes,[388-391] dietary abnormalities,[392-397] smoking,[398-400] and ethanol abuse[401]; in infants, they include the use of some drugs, perinatal aspiration syndrome,[322,402-405] hyperbilirubinemia,[406,407] phototherapy,[407,408] renal failure,[409] and hepatic failure.

Phototherapy. When platelets are exposed to a broad-spectrum blue fluorescent light in vitro, aggregation is decreased and microscopic alterations in granules and external membranes occur.[410]

Medications

ASPIRIN. Salicylate crosses the placenta and can be detected in fetuses after maternal ingestion.[351-354,411-415] Clearance of salicylate is slower in newborns than in adults, and thus infants have a potential risk of bleeding for a prolonged time.[352] However, in vitro studies have not demonstrated increased sensitivity of newborn platelets to salicylates as compared with adult platelets,[134,413] and the evidence linking maternal aspirin ingestion to clinically important bleeding in newborns is weak.[354] There is little reason to have serious concerns about maternal ingestion of aspirin, but it is reasonable to advise mothers to not ingest aspirin unless specifically instructed by their physician.

INDOMETHACIN. Indomethacin is used for nonsurgical closure of a patent ductus arteriosus in premature infants, but it also has antiplatelet activities. Indomethacin, like salicylate, has a longer half-life in newborns than in adults (21 to 24 hours in newborns vs. 2 to 3 hours in adults).[416] This extended half-life is probably due to underdevelopment of hepatic drug metabolism or renal excretory function or to altered protein binding.[417,418] Indomethacin inhibits platelet function in newborns, as shown by prolongation of bleeding times.[419,420] Randomized, controlled trials have provided conflicting conclusions on the effect of indomethacin on intraventricular hemorrhage in premature infants.[421]

Maternal Diabetes. The reactivity of platelets from diabetic mothers and their infants is increased, as demonstrated by enhanced thromboxane B_2 production, enhanced platelet aggregation,[390,422] and a lower threshold to many aggregating agents.[422] The enhanced platelet function in diabetes is associated with increased synthesis of a prostaglandin E–like substance that crosses the placenta and affects the fetus.[423] Despite these in vitro findings, the evidence linking enhanced platelet reactivity to clinically significant thromboembolism in newborns of diabetic mothers is weak.[424,425]

Diet. Alterations in the diet of mothers or infants during the postnatal period can affect newborn platelet function. Increases in the ratio of polyunsaturated fatty acids to saturated fatty acids in the diet of mothers who breastfeed their infants result in increases in the concentration of linoleic acid and enhanced thromboxane B_2 production.[392] Infants receiving a diet deficient in essential fatty acids may exhibit arachidonic acid depletion and platelet dysfunction.[393,395] Vitamin E functions as an antioxidant and as an inhibitor of platelet aggregation/release in humans.[396,397,426,427] Instances of vitamin E–deficient infants with increased platelet aggregation that reversed after vitamin E supplementation have been reported.[397,428]

Amniotic Fluid. Amniotic fluid contains procoagulant activity that enhances the generation of thromboxane A_2 by platelets.[402-405] Infants in whom perinatal aspiration syndrome develops have pulmonary hypertension with platelet thrombi in the pulmonary microcirculation. The exact mechanism or mechanisms leading to persistent pulmonary hypertension in these infants is unknown.

Nitric Oxide. Nitric oxide prevents adhesion of platelets to endothelial cells and inhibits ADP-induced aggregation of cord platelets in a manner similar to that in adults.[429-432]

Extracorporeal Membrane Oxygenation. Extracorporeal membrane oxygenation (ECMO) permits transfer of oxygen into blood across a semipermeable membrane and is currently used for infants with life-threatening severe respiratory insufficiency. Underlying respiratory disorders include meconium aspiration syndrome, severe RDS, congenital diaphragmatic hernia, persistent pulmonary hypertension, and sepsis. Hemorrhage, particularly ICH, is one of the most serious complications of this technique. Hardart and Fackler[433] reported an overall incidence of new ICH of about 10% in infants included in the Extracorporeal Life Support Organization Registry (N = 4550) from 1992 through 1995. Of 1398 evaluable premature infants (born at <37 weeks' EGA) reported to the registry between 1992 and 2000, ICH developed in 13%.[434] Similar to that found with cardiopulmonary bypass, the increased risk of bleeding during ECMO is due mostly to the use of heparin in combination with other hemostatic defects, including significantly decreased plasma concentrations of coagulation factors and platelet dysfunction secondary to chronic activation.[435-437] Other recognized contributing factors include prolonged hypoxia, ischemia, general anesthesia, acidosis, sepsis, and treatment with epinephrine.[433,435,438-443] In premature infants, the risk for ICH with ECMO correlates inversely with postconceptional age.[434] Although anticoagulation is required for ECMO, the optimal use of heparin has never been tested in clinical trials.

Thrombotic Disorders in Neonates

Congenital Prothrombotic Disorders

Patients with heterozygous defects for recognized inherited prothrombotic disorders are rarely seen with their first thromboembolic complication during childhood unless another pathologic event unmasks the problem. In contrast, patients who are homozygotes or double heterozygotes for a congenital prothrombotic disorder are often initially encountered in the newborn period or during early childhood. The following discussion is limited to the unique aspects of these inherited deficiencies in newborns. Chapter 33 discusses congenital prothrombotic disorders in detail.

Homozygous Prothrombotic Disorders. Though rare, the most commonly reported homozygous prothrombotic disorder encountered during the newborn period is protein C deficiency.[444-466] Homozygous protein S deficiency is even less common. All patients seen in the newborn period had undetectable levels of protein C (or protein S), whereas children with a delayed manifestation had detectable levels ranging between 0.05 and 0.20 U/mL. Rare cases of homozygous AT deficiency have been reported in newborns.[467]

Clinical Findings. The classic clinical manifestation of homozygous protein C/protein S deficiency consists of cerebral or ophthalmic damage (or both) in utero, purpura fulminans within hours or days of birth, and, on rare occasion, large-vessel thrombosis. Purpura fulminans is an acute, lethal syndrome of DIC characterized by rapidly progressive hemorrhagic necrosis of the skin secondary to dermal vascular thrombosis.[468-471] The skin lesions start as small, ecchymotic sites that increase in radial fashion, become purplish black with bullae, and then turn necrotic and gangrenous.[468,470,471] The lesions develop mainly on the extremities but can occur on the buttocks, abdomen, scrotum, and scalp. They also occur at pressure points, at sites of previous puncture, and at previously affected sites. Moreover, affected infants have severe DIC with hemorrhagic complications. Large-vessel arterial thromboses have been described in a neonate with homozygous AT deficiency.[467]

Diagnosis. The diagnosis of homozygous protein C/protein S deficiency in infants is based on the appropriate clinical picture, a protein C/protein S level that is usually undetectable, a heterozygous state in the parents, and, ideally, identification of the molecular defect. The presence of very low levels of protein C/protein S in the absence of clinical manifestations and a family history cannot be considered diagnostic, because physiologic plasma levels can be as low as 0.12 U/mL. Molecular diagnosis is available for identified families (see Chapter 33).

Initial Treatment. The diagnosis of homozygous protein C/protein S deficiency is usually unanticipated and made at the time of clinical evaluation. Although numerous forms of initial therapy have been used, 10 to

20 mL/kg of FFP every 6 to 12 hours is usually the form of therapy that is most readily available.[471,472] Plasma levels of protein C achieved with these doses of FFP vary from 15% to 32% at 30 minutes after the infusion and from 4% to 10% at 12 hours.[455] Plasma levels of protein S (which was entirely bound to C4b) were 23% at 2 hours and 14% at 24 hours, with an approximate half-life of 36 hours.[473]

A protein C concentrate (Ceprotin) received approval by the Food and Drug Administration in 2007 for use in treating congenital protein C deficiency. A second plasma-derived concentrate (Protexel) is also available in Europe. Recommended initial doses for acute thrombotic episodes and short-term prophylaxis in patients with severe protein C deficiency are 100 to 120 IU/kg in neonates, with subsequent doses of 60 to 80 IU/kg every 6 hours and maintenance doses of 45 to 60 IU/kg thereafter every 6 to 12 hours. However, dosing should be adjusted to maintain trough protein C activity of 50%. After resolution of the acute event, the patient should continue on a dose to maintain the trough protein C activity level above 25% for the duration of treatment. Replacement therapy should be continued until all the clinical lesions resolve, which usually takes place at 6 to 8 weeks. In addition to the clinical course, plasma D-dimer concentrations may be useful for monitoring the effectiveness of protein C replacement.[35,471]

Long-Term Therapy. Modalities used for the long-term management of infants with homozygous protein C/protein S deficiency include oral anticoagulation therapy, replacement therapy with either FFP or protein C concentrate, or liver transplantation.[463] When oral anticoagulation therapy is initiated, replacement therapy should be continued until the international normalized ratio (INR) is at a therapeutic value so that skin necrosis can be avoided. The therapeutic range for the INR can be individualized to some extent but is usually between 2.5 and 3.5. Risks associated with oral anticoagulation therapy include bleeding with high INR values and recurrent purpuric lesions with low INR values. Frequent monitoring of INR values is required if these complications are to be avoided. Bone development should also be monitored because the long-term effect of warfarin use on the bones of young infants is unknown. Long-term use of low–molecular-weight heparin (LMWH) could be considered, but it also has the potential for osteopenia. Moreover, it is expensive and requires twice-daily subcutaneous injections.

Heterozygous Prothrombotic Disorders. Thromboembolic events related to heterozygous genetic prothrombotic disorders rarely occur in infants. When they do, a secondary, acquired insult is usually present. The few case reports in the literature describe a diversity of clinical manifestations that usually reflect the site of the thrombus. Purpura fulminans did not occur in any case.[474-480]

Treatment. Treatment consists of supportive therapy alone, anticoagulation with heparin, thrombolytic therapy, and replacement with specific factor concentrates.[481,482] Removal or treatment of the secondary acquired insult is important. For AT deficiency, AT concentrates were administered to four infants as either boluses or continuous infusions. Boluses of 52 and 104 U/kg of AT concentrate increased AT levels from 0.10 U/mL to 0.75 and 1.48 U/mL, respectively, at 1 hour.[482] At 24 hours, levels of AT had decreased to approximately 0.20 U/mL. A continuous infusion of AT concentrate at a rate of 2.1 U/kg/hr maintained a plasma level of 0.40 to 0.50 U/mL.

Acquired Prothrombotic Disorders

Symptomatic secondary thromboembolic complications occur more frequently in sick newborns than in children of any other age, with an incidence of approximately 2.4 per 1000 hospital admissions to the NICU.[483] Intravascular catheters are responsible for more than 80% of venous and 90% of arterial thrombotic complications.[483] Their contribution to thrombosis is probably multifactorial, including the presence of a foreign surface, endothelial cell damage, impairment of flow, and infusion of noxious substances. Renal vein thrombosis (RVT) is the most common form of non–catheter-related thrombosis. Other risk factors include increased blood viscosity because of a high hematocrit, poor deformability of physiologically large red cells, dehydration, and activation of the coagulation and fibrinolytic systems secondary to a variety of medical problems. Very low AT levels have been observed in preterm infants with RDS, which probably contributed to their increased risk for thromboembolic complications.[38]

Venous Catheter–Related Thrombosis. The use of umbilical venous catheters and other forms of central venous catheters is associated with a significant risk for thrombosis.[483-485] According to autopsy studies, 20% to 65% of infants who die with an umbilical venous catheter in place have an associated thrombus. Appropriate placement of umbilical venous catheters is critical to prevention of serious organ impairment, such as portal vein thrombosis and hepatic necrosis. Long-term sequelae of umbilical venous catheters have not been rigorously studied but include portal vein thrombosis with portal hypertension, splenomegaly, gastric and esophageal varices, and hypertension. Until recently, pulmonary embolism was rarely diagnosed in sick newborns because its clinical signs were easily confused with those of RDS. Ventilation lung scintigraphy and computed tomography pulmonary angiography have been used in newborns to facilitate the diagnosis of pulmonary embolism, but there are no studies to date that have determined their sensitivity and specificity in this setting.[486,487]

Arterial Catheter–Related Thrombosis. Seriously ill infants require indwelling arterial catheters, which are associated with a risk of thrombosis regardless of the vessel or catheter type chosen.[488-492] Catheter-related thrombosis not only occludes catheters but may also obstruct major arterial vessels. In a retrospective examination of approximately 4000 infants who underwent umbilical artery catheterization, 1% had severe symptomatic vessel obstruction. Asymptomatic catheter-related thrombi occur more frequently, as evidenced by postmortem (3% to 59% of cases) and angiographic (10% to 90% of cases) studies.

Diagnosis. Contrast-enhanced angiography is considered the reference test for the diagnosis of arterial thrombosis. Noninvasive techniques such as Doppler ultrasound offer advantages, but their sensitivity and specificity are unknown. A review of 20 neonates with aortic thrombosis treated in one institution revealed that ultrasound failed to identify thrombi in four patients, three of whom had complete aortic obstruction.[491]

Sequelae. The sequelae of catheter-related thrombosis can be immediate or long term. Acute symptoms reflect the location of the catheter and include renal hypertension, intestinal necrosis, and peripheral gangrene.[493] The long-term side effects of symptomatic and asymptomatic thrombosis of major vessels have not been studied but are probably significant.

Prophylaxis with Heparin. A low-dose continuous heparin infusion (3 to 5 U/hr) is commonly used to maintain catheter patency. The effectiveness of heparin was assessed in seven studies focusing on three outcomes: patency, local thrombus, and ICH.[489,490,492,494-496] Patency, which is probably linked to the presence of local thrombus, is prolonged with the use of low-dose heparin. Local thrombosis was assessed by ultrasound in two randomized studies. The evidence linking low-dose heparin prophylaxis to ICH in newborns is weak.[492,497,498] One study had a sample size of only 15 per arm[492]; another case-control study had a broad odds ratio that ranged from 1.4 to 11[497]; and a third study was a retrospective association analysis that may be confounded by other variables.[498] A randomized study involving 113 premature infants using a 1-U/hr continuous heparin infusion showed no difference in ICH.[499] Thus the magnitude of risk for ICH is uncertain. Heparin is used in at least three quarters of American nurseries.[493]

Renal Vein Thrombosis. RVT occurs primarily in newborns and young infants. Approximately 80% of cases occur within the first month and usually within the first week of life. In some infants RVT develops in utero. The incidence in male and female infants is similar, and the left and right sides are affected equally. Bilateral thrombosis occurs in 24% of pediatric RVT patients.

Clinical Findings and Etiology. The initial symptoms and clinical findings are different in neonates and older patients and are influenced by the extent and rapidity of thrombus formation. Neonates generally have a flank mass, hematuria, proteinuria, thrombocytopenia, and impaired function of the involved kidney. Clinical findings suggesting acute inferior vena cava thrombosis include cold, cyanotic, and edematous lower extremities. RVT results from pathologic states characterized by reduced renal blood flow, increased blood viscosity, hyperosmolality, or hypercoagulability.

Coagulation Abnormalities. The most common coagulation abnormality in RVT is thrombocytopenia, which is usually mild, with average values of 100×10^9/L. Thus RVT should be considered in the differential diagnosis of thrombocytopenia in neonates. Coagulation may be prolonged and levels of fibrinogen-fibrin degradation products increased. Children with RVT are often evaluated for a congenital prothrombotic disorder, although the significance of thrombophilic markers in this disease is unknown.[476]

Diagnosis and Treatment. Ultrasound is the radiographic test of choice for the diagnosis of RVT because of ease of testing and sensitivity to an enlarged kidney. Treatment options include supportive care, anticoagulation, and thrombolytic therapy. The use of anticoagulants and thrombolytic agents is controversial. Evidence-based guidelines have recently been published.[2] Either supportive care with serial radiographic monitoring or heparin therapy with therapeutic doses for 6 weeks to 3 months should be considered for unilateral RVT in the absence of uremia and extension into the inferior vena cava. Heparin therapy with therapeutic doses for 6 weeks to 3 months is recommended for unilateral RVT that extends into the inferior vena cava or for bilateral RVT because of the risk of pulmonary embolism and complete renal failure. Thrombolytic therapy should be considered in the presence of bilateral RVT and renal failure. Thrombectomy, though a common therapeutic choice in the past, is rarely indicated.

Outcome. RVT has changed from a frequently lethal complication to one that is now associated with nearly 100% survival.[2,500,501,502-504] However, there are considerable long-term renal sequelae,[500,502-505] with approximately 70% of affected kidneys having irreversible atrophy, approximately 20% of children having hypertension, and approximately 3% of children having chronic renal failure.[501]

Spontaneous Venous and Arterial Thrombosis. Spontaneous venous thrombosis occurs in the adrenal veins, inferior vena cava, portal vein, hepatic veins, and venous system of the brain.[493,506] Spontaneous occlusion of arterial vessels in the absence of a catheter is unusual, but it can occur in ill infants. As in catheter-related thrombosis, the clinical findings reflect the vessel that is occluded. Complete occlusion of a vessel can lead to gangrene and loss of the affected limb or to ischemic organ damage. The presence of systemic hypertension in newborns is frequently related to renal artery thrombosis, even in the absence of a catheter.

Anticoagulation Therapy in Newborns

Heparin Therapy in Newborns. Guidelines for antithrombotic therapy in neonates have been published.[2,507] However, the limited strength of the recommendations reflects the lack of controlled trials in this area. Recommendations for adult patients provide useful guidelines but probably do not reflect the optimal therapy for newborns. Current therapeutic options include supportive care alone, anticoagulant therapy, thrombolytic therapy, and thrombectomy. For most infants in whom thrombotic complications develop, the cause of thrombosis is a catheter-related thrombus that does not produce clinical symptoms. In most nurseries, catheters are not routinely checked for associated thrombosis; thus, by exclusion, most infants with clinically silent thrombi receive supportive care alone.

Age-Dependent Features. Although the benefits of heparin therapy in newborns are probably similar to those in adults, the relative risk that major bleeding will occur with its use may be increased. Infants with thromboses that are extending or infants whose organ or limb viability is threatened by thrombosis may benefit from heparin therapy.

Heparin's anticoagulant activities are mediated primarily through acceleration of inhibition of thrombin and factor Xa by AT. Although dosing for heparin therapy in newborns differs from that in adults, optimal dosing cannot be predicted. Several observations suggest that the heparin requirements of neonates are decreased in comparison to those of adults. First, the capacity of plasma from healthy newborns to generate thrombin is both delayed and decreased in comparison to that of adult plasma, but similar to that of plasma from adults receiving therapeutic amounts of heparin.[508,509] Second, at heparin concentrations in the therapeutic range, the capacity of plasma from healthy newborns to generate thrombin is barely measurable.[510] Third, the amount of clot-bound thrombin is decreased in newborns because low plasma concentrations of prothrombin probably reduce heparin requirements.[511] Observations suggesting higher heparin requirements include the following: (1) clearance of heparin is accelerated in newborns,[38,512,513] and (2) plasma concentrations of AT are decreased to levels frequently less than 0.40 in premature infants, which may limit heparin's antithrombotic activities.[18,21,26,482,514]

Therapeutic Range and Dose. Therapeutic ranges reflect the optimal risk-benefit ratio of anticoagulant therapy with regard to recurrent thrombotic events and bleeding complications. In the absence of clinical trials in newborns, one approach is to use heparin in doses that achieve the lower therapeutic range for adults (see Chapter 33).

General guidelines for initial dosing and subsequent dose adjustment of unfractionated heparin in full-term and premature neonates have been published.[2,507,515] Average doses of heparin required in newborns are bolus doses of 25 to 100 U/kg, depending on gestational age, and average maintenance doses of 15 to 28 U/kg/hr, again depending on gestational age. Adjustments are made most reliably with heparin assays, with a target-level anti-Xa range of 0.35 to 0.70 U/mL. Because of the short half-life of unfractionated heparin, simple discontinuation of the infusion is typically sufficient to reverse anticoagulation in the event of hemorrhage. For more rapid reversal, protamine sulfate can be used to neutralize heparin in vivo. However, anaphylactoid reactions with hypotension and bradycardia have been associated with protamine use in children and adults, and protamine should therefore be used with caution.[516]

The use of LMWH offers significant therapeutic advantages over unfractionated heparin, and there is now considerable experience using these preparations in newborns.[2,493,515,517,518] Potential advantages include more predictable pharmacokinetics, the need for less frequent monitoring than with unfractionated heparin, ease of administration, decreased bleeding, and possibly a lower incidence of heparin-induced thrombocytopenia. Full-term and moderately preterm (28 to 36 weeks EGA) infants metabolize heparin at considerably faster rates than older children and adults do and typically require higher doses to maintain the same levels. Very premature infants (<28 weeks) have similar pharmacokinetic parameters for heparin as do older children and adults. General guidelines for initial therapeutic dosing and subsequent sliding-scale dose adjustments of LMWH in neonates of different gestational ages have been published.[2,507,515] Typically, higher doses of LMWH are required in neonates compared with adults to achieve the same anti-Xa levels. Traditional doses of enoxaparin in full-term neonates for full anticoagulation are 1.5 mg/kg given subcutaneously every 12 hours,[2,507] but they can be as high as 2 mg/kg given subcutaneously every 12 hours in preterm neonates.[507] Levels should be monitored with anti-Xa heparin assays on samples drawn via fresh venipuncture 4 to 6 hours after the subcutaneous dose is given to achieve levels of 0.5 to 1 U/mL for full therapeutic dosing. Levels should be checked every two to four doses for the first week of therapy, then once a week for a month, and then monthly if the infant is stable.[515] Infants who do not respond appropriately to heparin therapy, despite adequate levels, may benefit from infusions of AT concentrate, even if the levels are close to the normal physiologic range for their age.[515] Intramuscular and arterial puncture and the use of antiplatelet medications should be avoided in newborns receiving heparin therapy, and platelet counts should be monitored periodically.

Like unfractionated heparin, LMWH can be reversed with the use of protamine, with dosing dependent on the last dose of LMWH given.[2,519,520] As discussed earlier, protamine must be given slowly, and caution must be exercised to avoid potential hypersensitivity reactions. Repeat doses of protamine may be required to reverse the effects of LMWH because the half-life of protamine is relatively shorter than that of LMWH.

Close monitoring of the thrombus with objective means such as ultrasound is recommended. The duration of heparin therapy required for the treatment of thromboembolic complications is uncertain. One approach is to treat the infant for 10 to 14 days with heparin alone. If there is subsequent extension of the thrombus in the absence of anticoagulation therapy, treatment with oral anticoagulants may be considered.

Adverse Effects. There are two clinically important adverse effects of heparin therapy: hemorrhage, including ICH, and heparin-induced thrombocytopenia.[521,522] In the absence of an alternative cause, thrombocytopenic patients should be evaluated for heparin-induced thrombocytopenia and treated with alternative therapies.

Oral Anticoagulant Therapy in Newborns

Age-Dependent Features. Oral anticoagulation therapy in children is discussed in Chapter 33, and only specific issues related to newborns are discussed in this section. The oral anticoagulant warfarin works by reducing functional plasma levels of the VK-dependent proteins. At birth, levels of the VK-dependent proteins are similar to those found in adults receiving therapeutic amounts of warfarin for deep venous thrombosis/pulmonary embolism.[18,21,26,92,510,523,524] In addition, stores of VK are low, and a small number of newborns have evidence of functional VK deficiency.[65] These features significantly increase the sensitivity of newborns to warfarin and potentially their risk for bleeding. Oral anticoagulant therapy should be avoided when possible during the first month of life.[65,525] Unfortunately, a small number of infants require extended anticoagulation therapy, and heparin cannot be used for extended periods because of the risk of osteopenia.

Indications, Therapeutic Range, and Dose. The optimal therapeutic INR range is unknown for newborns and almost certainly differs from that for adults.[2] Recommendations for oral anticoagulation therapy in adults can be used as a guideline for determining the lowest effective dose, which to some extent can be individualized. Maintenance doses for warfarin are age dependent, with infants requiring the highest doses (0.32 mg/kg).[526]

Adverse Effects. Close monitoring of oral anticoagulation in newborns is required if both hemorrhagic and recurrent thrombotic complications are to be prevented. Unfortunately, these infants often have poor venous access, as well as complicated medical problems. Weekly or biweekly INR measurements and frequent dose adjustments are required.[527] Doses are affected by diet, medications, and intercurrent illnesses. Breastfed infants are very sensitive to oral anticoagulants because of low concentrations of VK in breastmilk.[53,59,72,298,528] Daily supplementation of breastfed infants with small amounts of commercial formulas reduces their sensitivity to oral anticoagulants and the risk of sudden increases in INR values. In contrast to breastfed infants, infants receiving commercial formulas or total parenteral nutrition are resistant to oral anticoagulants because of VK supplementation.[298,529] Reducing or removing VK supplementation in infants receiving total parenteral nutrition significantly decreases the dose requirements. Most infants requiring oral anticoagulants also require other medications on an intermittent and long-term basis. The effects of dosage changes and the introduction of new medications must be closely supervised.

Antiplatelet Agents in Newborns. Antiplatelet agents are rarely used in newborns for antithrombotic therapy. The hyporeactivity of neonatal platelets and the paradoxically short bleeding time suggest that optimal use of antiplatelet agents differs in newborns and adults. Aspirin is the most commonly used antiplatelet agent. The empiric use of low doses of 1 to 5 mg/kg/day has been proposed as adjuvant therapy for patients with Blalock-Taussig shunts, some endovascular stents, and some thrombotic cerebrovascular events.[530] Use of the antiplatelet agent clopidogrel (Plavix) in infants as young as 6 weeks of age has been reported in a small retrospective series.[531] A prospective, multicenter, placebo-controlled pharmacodynamic trial of clopidogrel in children (from birth to 24 months) with a cardiac condition demonstrated that a dose of 0.20 mg/kg/day achieved a platelet inhibition level similar to that in adults receiving a standard dose of 75 mg/day, although there was significant interpatient variability in platelet inhibition levels.[532,533] Clopidogrel was well tolerated by the infants.

Thrombolytic Therapy in Newborns

Age-Dependent Features. The activity of thrombolytic agents depends on endogenous concentrations of plasminogen, which are physiologically decreased at birth.[534] Low plasminogen levels result in impairment of the capacity to generate plasmin[73] and a decrease in the capacity to thrombolyse fibrin clots.[534] In addition, fetal glycoforms of plasminogen are less efficiently converted to plasmin by tPA than is adult plasminogen.[76] Thus neonates have an overall reduced capacity to respond to tPA in comparison with adults. If an infant's condition does not respond to thrombolytic therapy, replacement of plasminogen should be considered.

Indications, Therapeutic Range, and Dose. Infants in whom serious thrombotic complications develop, as defined by organ or limb impairment, may benefit from thrombolytic therapy. The clinical objective is removal of the clot as quickly and safely as possible. Surgical removal of a clot in a major vessel can be curative; however, it is technically difficult and poses a considerable life-threatening risk to infants, who are often premature. In the absence of contraindications, the use of thrombolytic agents in these infants is a preferred approach (see Chapter 33).

CONCLUSION

Over the past several decades, the developmental timing and functional maturation of the human hemostatic system have been examined in great detail. These studies show critically important differences in many components of the hemostatic system in premature and full-term newborns versus older children and adults. The reason for this unique physiologic state in the fetus and neonate is not clear but appears to be appropriately balanced for healthy full-term infants. Of clinical importance has been the determination of gestational and postnatal age-specific activity ranges of factors involved in hemostasis, which has allowed appropriate interpretation of clinical data. As newer diagnostic tests and treatments are introduced for older children and adults, it will be critical to carefully evaluate them separately in the context of neonates, both premature and full-term, given their unique physiologic state.

ACKNOWLEDGMENT

The author would like to acknowledge Dr. Paul Monagle and the late Dr. Maureen Andrew for their chapter on developmental hemostasis contained in previous editions of this textbook. Their work formed the basis for the current chapter. The author would also like to thank Dr. Ellis Neufeld, Dr. Marilyn Manco-Johnson, Dr. Martha Sola-Visner, and Dr. Bob Montgomery for helpful advice.

   This is a useful evidence-based guideline from a panel of experts providing recommendations for preventative and therapeutic management of thrombosis in the neonate and child. It includes specific recommendations regarding neonatal renal vein thrombosis, umbilical catheter thromboprophylaxis, sinus venous thrombosis, and purpura fulminans, as well as general recommendations regarding neonatal thrombosis management. Guidelines for neonatal heparin dosing and monitoring are provided.

3. Forestier F, Daffos F, Galacteros F, et al: Hematological values of 163 normal fetuses between 18 and 30 weeks of gestation. *Pediatr Res* 20:342–346, 1986.

   This study provides reference values for coagulation factors II, V, VIII, and IX from 103 healthy human fetuses between 19 and 27 weeks' gestation.

17. Reverdiau-Moalic P, Delahousse B, Body G, et al: Evolution of blood coagulation activators and inhibitors in the healthy human fetus. *Blood* 88:900–906, 1996.

    This study provides reference values for screening coagulation tests, coagulation factor levels, and inhibitors of coagulation in 285 healthy human fetuses from 19 to 38 weeks' gestation. It documents changes that occur in these levels during human embryonic development.

18. Andrew M, Paes B, Milner R, et al: Development of the human coagulation system in the full-term infant. *Blood* 70:165–172, 1987.

    This is a classic paper providing reference values for coagulation tests and inhibitors of coagulation in healthy full-term newborns over the first 6 months of life using the ACL analyzer system. It provided evidence for the developmental maturation of the hemostasis system during the neonatal and infancy periods.

19. Monagle P, Barnes C, Ignjatovic V, et al: Developmental haemostasis. Impact for clinical haemostasis laboratories. *Thromb Haemost* 95:362–372, 2006.

    This study provides updated reference values for coagulation screening tests, coagulation factors, inhibitors of coagulation, and D-dimer levels for healthy full-term newborns, infants, and children using the STA Compact analyzer and Diagnostica Stago reagent system, which is more common in current laboratory use than the systems used in the earlier studies by Andrew and colleagues in the 1980s. It also highlights differences in absolute reference range values obtained, depending on anlayzer and reagents used.

20. Appel IM, Grimminck B, Geerts J, et al: Age dependency of coagulation parameters during childhood and puberty. *J Thromb Haemost* 10:2254–2263, 2012.

    This study provides reference values for coagulation screening tests, coagulation factors, D-dimer levels, von Willebrand factor, and fibrinolytic factors in healthy full-term newborns and infants using the Sysmex CA-1500 and Behring BCS analyzer systems with reagents from Siemens Healthcare Diagnostics Products GmbH.

21. Andrew M, Paes B, Johnston M: Development of the hemostatic system in the neonate and young infant. *Am J Pediatr Hematol Oncol* 12:95–104, 1990.

    This paper summarizes changes in screening coagulation tests, coagulation factor levels, coagulation inhibitor levels, and fibrinolytic system component levels in healthy full-term infants during the first 6 months of life as determined using the ACL analyzer system. It also provides values for healthy fetuses (19 to 27 weeks' gestational age) and premature infants at birth (28 to 31 weeks' gestational age).

22. Andrew M, Vegh P, Johnston M, et al: Maturation of the hemostatic system during childhood. *Blood* 80:1998–2005, 1992.

    This paper provides reference values for screening coagulation tests, coagulation factor levels, coagulation inhibitor levels, and fibrinolytic system components in children of 1 to 16 years of age and compares them with values obtained from adults. They show continued maturation of the hemostatic system during childhood.

23. Monagle P, Ignjatovic V, Savoia H: Hemostasis in neonates and children: pitfalls and dilemmas. *Blood Rev* 24:63–68, 2010.

    This review article highlights the challenges of laboratory assessment of hemostasis in neonates. It provides a useful summary of studies demonstrating age-related differences in coagulation and implications for monitoring anticoagulation therapy in children.

26. Andrew M, Paes B, Milner R, et al: Development of the human coagulation system in the healthy premature infant. *Blood* 72:1651–1657, 1988.

    This is one of the original studies that defined the postnatal normal reference range for coagulation screening tests, coagulation factor levels, and coagulation inhibitor levels in healthy premature infants. It demonstrates an accelerated postnatal maturation toward adult levels compared with full-term infants.

28. Manco-Johnson MJ: Development of hemostasis in the fetus. *Thromb Res* 115(Suppl 1):55–63, 2005.

    This review article summarizes developmental expression of the hemostatic system components during fetal development. It discusses the unique aspects of fetal-maternal vitamin K biology.

72. Aballi AJ, De Lamerens S: Coagulation changes in the neonatal period and in early infancy. *Pediatr Clin North Am* 9:785–817, 1962.

    This is one of the first reports of developmental stage–specific differences in coagulation parameters in neonates and young infants compared with older children and adults.

83. Weinstein MJ, Blanchard R, Moake JL, et al: Fetal and neonatal von Willebrand factor (vWF) is unusually large and similar to the vWF in patients with thrombotic thrombocytopenic purpura. *Br J Haematol* 72:68–72, 1989.

    This report demonstrates the presence of unusually large von Willebrand factor multimers in the fetal circulation at birth and shortly after delivery. The size of these multimers is similar to those found in endothelial cell Weibel-Palade bodies, platelet alpha granules, and the plasma of patients with thrombotic thrombocytopenic purpura.

86. Schmugge M, Dunn MS, Amankwah KS, et al: The activity of the von Willebrand factor cleaving protease ADAMTS-13 in newborn infants. *J Thromb Haemost* 2:228–233, 2004.

    This study examines ADAMTS-13 activity in cord blood and neonatal venous blood (ages 2 to 3 days) from healthy full-term newborns and reports reduced activity (mean, 53% ± 1.1%) compared with adults in about 25% of study subjects.

90. Sola-Visner M: Platelets in the neonatal period: developmental differences in platelet production, function, and hemostasis and the potential impact of therapies. *Hematology Am Soc Hematol Educ Program* 2012:506–511, 2012.

    This review article summarizes the differences between fetal/neonatal and adult thrombopoiesis and discusses implications for neonatal clinical care.

107. Rajasekhar D, Kestin AS, Bednarek FJ, et al: Neonatal platelets are less reactive than adult platelets to physiological agonists in whole blood. *Thromb Haemost* 72:957–963, 1994.

     This is representative of a number of research articles demonstrating the relative hyporesponsiveness to physiologic agonists of neonatal versus adult platelets.

124. Israels SJ, Rand ML, Michelson AD: Neonatal platelet function. *Semin Thromb Hemost* 29:363–372, 2003.

     This review article summarizes data demonstrating decreased intrinsic platelet activation in heatlhy neonates and discusses how this may be compensated for by increased platelet adhesion from higher levels of circulating ultralarge von Willebrand Factor multimers.

148. Buchanan GR: Coagulation disorders in the neonate. *Pediatr Clin North Am* 33:203–220, 1986.

     This is a review article that highlights hemostatic differences between neonates and older children. It includes practical approaches to the investigation of bleeding disorders in the newborn.

153. Kulkarni R, Ponder KP, James AH, et al: Unresolved issues in diagnosis and management of inherited bleeding disorders in the perinatal period: a White Paper of the Perinatal Task Force of the Medical and Scientific Advisory Council of the National Hemophilia Foundation, USA. *Haemophilia* 12:205–211, 2006.

This is an expert panel position paper from the National Hemophilia Foundation that summarizes perinatal issues related to inherited bleeding disorders and identifies current clinical challenges. It includes discussion of obstetric considerations, mode of delivery, incidence of neonatal intracranial hemorrhage, factor replacement, and other related topics.

161. Ignjatovic V, Kenet G, Monagle P: Developmental hemostasis: recommendations for laboratories reporting pediatric samples. *J Thromb Haemost* 10:298–300, 2012.

This is an up-to-date assessment of the challenges involved in laboratory diagnosis of hemostasis disorders in the newborn. It highlights the significant variability in test results depending on patient population as well as reagents and analyzers used. It emphasizes the need to use appropriate reference ranges to properly interpret data.

163. Del Vecchio A, Latini G, Henry E, et al: Template bleeding times of 240 neonates born at 24 to 41 weeks' gestation. *J Perinatol* 28:427–431, 2008.

This study documents longer template bleeding times in preterm infants compared with term infants when measured on the first day of life.

184. Chalmers E, Williams M, Brennand J, et al: Guideline on the management of haemophilia in the fetus and neonate. *Br J Haematol* 154:208–215, 2011.

This document provides evidence-based recommendations for the perinatal management of fetuses and neonates with hemophilia. It reflects the consensus opinion of the United Kingdom Haemophilia Centre Doctor's Organization (UKHC-DO) and the Haemostasis Task Force of the British Committee for Standards in Haematology (BCSH).

248. Townsend C: The haemorrhagic disease of the newborn. *Arch Pediatr* 11:559, 1894.

This classic article represents the first written description of hemorrhagic disease of the newborn.

293. American Academy of Pediatrics Committee on Fetus and Newborn: Policy statement: controversies concerning vitamin K and the newborn. *Pediatrics* 112:191–192, 2003.

This policy statement from the American Academy of Pediatrics provides recommendations for the use of vitamin K in the prevention of early and late vitamin K–deficiency bleeding in the newborn.

326. Roberts I, Stanworth S, Murray NA: Thrombocytopenia in the neonate. *Blood Rev* 22:173–186, 2008.

This is a useful review article that describes the differential diagnosis of thrombocytopenia in the neonate and provides general principles for the management of neonatal thrombocytopenia.

327. Del Vecchio A, Motta M: Evidence-based platelet transfusion recommendations in neonates. *J Matern Fetal Neonatal Med* 24(Suppl 1):38–40, 2011.

This review article discusses current practices regarding prophylactic platelet transfusions in thrombocytopenic neonates and provides recommendations for transfusion management based on clinical scenario and platelet count.

335. Bussel JB, Primiani A: Fetal and neonatal alloimmune thrombocytopenia: progress and ongoing debates. *Blood Rev* 22:33–52, 2008.

This is a comprehensive review article on the clinical presentation, specific antigen incompatibilities, predictors of disease, risk of intracranial hemorrhage, and recommendations for testing and risk-stratified management of neonatal alloimmune thrombocytopenia.

360. Balduini CL, Pecci A, Noris P: Diagnosis and management of inherited thrombocytopenias. *Semin Thromb Hemost* 39:161–171, 2013.

This is a useful review article that provides a detailed differential diagnosis of inherited thrombocytopenias. It includes known genetic abnormalities, disease characteristics, representative peripheral blood smear images, algorithms for evaluation, and recommendations for management.

471. Goldenberg NA, Manco-Johnson MJ: Protein C deficiency. *Haemophilia* 14:1214–1221, 2008.

This is a comprehensive review article that discusses the clinical presentation, diagnosis, management, prognosis, and complications of protein C deficiency.

501. Lau KK, Stoffman JM, Williams S, et al: Neonatal renal vein thrombosis: review of the English-language literature between 1992 and 2006. *Pediatrics* 120:e1278–e1284, 2007.

This article presents a comprehensive literature review and metaanalysis regarding patient characteristics, presentation, prothrombotic risk factors, treatment modalities, and outcomes of neonates with renal vein thrombosis.

507. Saxonhouse MA: Management of neonatal thrombosis. *Clin Perinatol* 39:191–208, 2012.

This review articles addresses common neonatal thrombotic events and discusses presentation, risk factors, diagnostic approaches, and management recommendations. It contains tables listing recommended dosages of unfractionated heparin, low–molelcular-weight heparin, and recombinant tissue plasminogen activator in neonates.

515. Manco-Johnson MJN, Nuss R: Neonatal thrombotic disorders. *NeoReviews* 1:e201–e205, 2000.

This is a minireview article that describes salient features, suggested readings, and self-assessment quiz questions related to neonatal thrombotic disorders. It provides tables with recommended dosing scales and monitoring for unfractionated heparin, low–molecular-weight heparin, and recombinant tissue plasminogen activator in neonates.

From Andrew M, Paes B, Milner R, et al: Development of the human coagulation system in the full-term infant. Blood *70:165–172, 1987.*

APTT, Activated partial thromboplastin time; *HMWK*, high–molecular-weight kininogen; *INR*, international normalized ratio; *PK*, prekallikrein; *PT*, prothrombin time; *TCT*, thrombin clotting time; *VWF*, von Willebrand factor.

[*] All factors except fibrinogen are expressed as units per milliliter, with pooled plasma containing 1 U/mL. All values are expressed as means, followed by the lower and upper boundary encompassing 95% of the population. Between 40 and 77 samples were assayed for each value in newborns. Some measurements were skewed because of a disproportionate number of high values. All infants received 1 mg of vitamin K intramuscularly at birth. The following reagents were used for coagulation screening tests: prothrombin time (Dade C rabbit thromboplastin), activated partial thromboplastin time (Dade FS). Measurements were made with an ACL analyzer.

[†] Values indistinguishable from those of adults.

TABLE A5-3 Reference Values for Coagulation Tests in Healthy Full-Term Infants and Children with the STA Analyzer[*]

Coagulation Tests	Age 1 Day	Age 3 Days	Age 1 Month to 1 Year	Age 1 to 5 Years	Age 6 to 10 Years	Age 11 to 16 Years	Adults

Reproduced with permission from Monagle P, Barnes C, Ignjatovic V, et al: Developmental haemostasis: impact for clinical haemostasis laboratories. Thromb Haemost *95:362–372, 2006.*

APTT, Activated partial thromboplastin time; *AT*, antithrombin; *INR*, international normalized ratio; *PT*, prothrombin time.

[*] Values represent means. Boundaries including 95% of the population are shown in parentheses. All infants received 1 mg of vitamin K intramuscularly at the time of birth.

[†] STA-PTT-A reagent used.

[‡] Denotes values that are significantly different from adult values ($P < .05$).

[§] Neoplastine Cl reagent used.

TABLE A5-4 Reference Values for Coagulation Tests in Healthy Premature Infants (30 to 36 Weeks' Gestation) During First 6 Months of Life[*]

Coagulation Tests	Day 1	Day 5	Day 30	Day 90	Day 180	Adult

From Andrew M, Paes B, Milner R, et al: Development of the human coagulation system in the healthy premature infant. Blood *72:1651–1657, 1988.*

APTT, Activated partial thromboplastin time; *Factor VIII*, factor VIII procoagulant; *HMWK*, high–molecular-weight kininogen; *INR*, international normalized ratio; *PK*, prekallikrein; *PT*, prothrombin time; *TCT*, thrombin clotting time; *VWF*, von Willebrand factor.

[*] All factors except fibrinogen are expressed as units per milliliter, with pooled plasma containing 1 U/mL. All values are given as means, followed by the lower and upper boundary encompassing 95% of the population. Between 40 and 96 samples were assayed for each value in newborns. Some measurements were skewed because of a disproportionate number of high values. All infants received 1 mg of vitamin K intramuscularly at birth. The following reagents were used for coagulation screening tests: prothrombin time (Dade C rabbit thromboplastin), activated partial thromboplastin time (Dade FS). Measurements were made with an ACL analyzer.

[†] Values indistinguishable from those of adults.

[‡] Measurements are skewed because of a disproportionate number of high values.

TABLE A5-5 Reference Values for Coagulation Tests in Healthy Children (Ages 1 to 16 Years) and Adults[*]

Coagulation Tests	Age 1 to 5 Years	Age 6 to 10 Years	Age 11 to 16 Years	Adult

From Andrew M, Paes B, Johnston M: Development of the hemostatic system in the neonate and young infant. Am J Pediatr Hematol Oncol *12:95–104, 1990.*

PAI-1, Plasminogen activator inhibitor 1; *tPA*, tissue plasminogen activator.

[*] Plasminogen units are those recommended by the Committee on Thrombolytic Agents. Values for tPA are given as nanograms per milliliter. For α_2-antiplasmin, values are expressed as units per milliliter, with pooled plasma containing 1 U/mL. Values for PAI-1 are given as units per milliliter, with 1 unit of PAI-1 activity being defined as the amount of PAI-1 that inhibits the 1 IU of human single-chain tPA. All values are given as means, followed by the lower and upper boundaries encompassing 95% of the population.

[†] Values indistinguishable from those of adults.

[‡] Values different from those of full-term infants.

CHAPTER 6

Acquired Aplastic Anemia and Pure Red Cell Aplasia

Akiko Shimamura and **David A. Williams**

CHAPTER OUTLINE

APLASTIC ANEMIA
Epidemiology
Causal Factors
Pathophysiology
Clinical Evaluation
Management and Outcome
PURE RED CELL APLASIA
Primary Acquired Pure Red Cell Aplasia
Secondary Acquired Pure Red Cell Aplasia

Acquired and congenital bone marrow failure syndromes are characterized by a reduction in the effective production of mature erythrocytes, granulocytes, and platelets by the bone marrow. Bone marrow failure leads to various peripheral blood cytopenias. In some conditions, only one or two cell lines may be affected. In others such as aplastic anemia the result is pancytopenia. In this chapter, we deal only with the acquired bone marrow failure syndromes, though we use the term rather loosely because the acquired marrow failure syndromes may have a genetic basis. The known *inherited/congenital* bone marrow failure syndromes are described in detail in Chapter 7. The acquired marrow failure syndromes that affect only platelets or granulocytes are described in Chapters 22 and 34 respectively. The acquired single lineage deficiency syndromes that involve red cell production (pure red cell aplasia) are also described in this chapter, except that the 5Q-syndrome is discussed in Chapter 7 and in more detail Chapter 51.

APLASTIC ANEMIA

Decreased production of *mature blood cells* may result from a reduction in the number or function of their *progenitors*. *Aplastic anemia* is a descriptive term referring to a clinical state in which peripheral blood pancytopenia results from reduced or absent production of blood cells in the bone marrow. Aplastic anemia may arise in the setting of inherited/congenital syndromes associated with a predisposition to marrow failure (discussed in Chapter 7), may develop secondary to marrow-toxic stressors in an otherwise seemingly normal host, or may lack any apparent underlying cause. Classifications of the aplastic anemias are presented in Box 6-1. A careful medical history, physical examination, and laboratory evaluation are critical to discern inherited versus acquired causes of aplastic anemia. The distinction between inherited and acquired causes of aplastic anemia carries profound implications for medical management and treatment, so a careful search for possible underlying inherited syndromes should be undertaken prior to initiation of therapy.

Camitta and co-workers classified the severity of aplastic anemia in an effort to make possible the comparison of diverse groups of patients and different therapeutic approaches.[1] Diagnosis of *severe aplastic anemia* requires that the patient have at least two of the following anomalies: a granulocyte count below 500/μL, a platelet count below 20,000/μL, and an absolute reticulocyte count less than or equal to 40×10^9/L. In addition the bone marrow biopsy must contain less than 25% of the normal cellularity or less than 30% hematopoietic elements (Fig. 6-1). Very severe aplastic anemia is further defined by a granulocyte count of less than 200/μL.[2] *Mild* or *moderate aplastic anemia*, sometimes called *hypoplastic anemia*, is distinguished from the severe form by the presence of mild or moderate cytopenias and more variable, but still deficient, bone marrow cellularity. These distinctions are more than semantic; they are critical for the prediction of outcome and the choice of therapy.

Epidemiology

Epidemiologic studies performed in Europe estimate that the annual incidence of aplastic anemia is 2 per million per year.[3] By comparison, the incidence of acute leukemia is about 50 per million per year. Higher figures for the

Box 6-1 Classification of the Aplastic Anemias[339]

ACQUIRED

- Secondary
  - Radiation
  - Drugs and chemicals
    - Direct toxicity: chemotherapy; benzene
    - Idiosyncratic: chloramphenicol; antiinflammatory drugs; antiepileptics; carbonic anhydrase inhibitors
  - Viruses
    - Epstein-Barr virus
    - Hepatitis (non-A, B, C, E, or G)
    - Human immunodeficiency virus
  - Immune diseases
    - Eosinophilic fasciitis
    - Hypoimmunoglobulinemia
    - Systemic lupus erythematosis (uncommon)
    - Thymoma
    - Graft-versus-host disease in immunodeficiency
  - Pregnancy
  - Paroxysmal nocturnal hemoglobinuria
  - Myelodysplasia
- Idiopathic

INHERITED

- Fanconi anemia
- Dyskeratosis congenita
- Shwachman-Diamond syndrome
- Amegakaryocytic thrombocytopenia
- Diamond-Blackfan anemia
- Reticular dysgenesis
- GATA-2 syndromes
- Familial aplastic anemias
- Nonhematologic syndromes (e.g., Down, Dubowitz, and Seckel syndromes)

incidence of aplastic anemia have been obtained from smaller studies in the United States and earlier surveys in Europe, but these figures may have been inflated by the inclusion of cases of myelodysplasia, a much more common syndrome. Aplastic anemia is more common in Asia (4 to 7 per million per year)[4] than in the West. Chloramphenicol, a known cause of aplastic anemia, has been widely used in much of Asia because of its efficacy and low cost, but reductions in its use have not been accompanied by reductions in aplastic anemia incidence in Japan[5,6] or elsewhere,[7,8] and no association was observed in the case control studies in Thailand.[9] A recent case control study[10] in Thailand spanning 1989-2002 described an association between aplastic anemia and exposure to benzene or pesticides. Although an increased risk of aplastic anemia was also associated with animal exposures and ingestion of nonbottled or nondistilled water, no significant associations with known infections or hepatitis were observed.

The peak age of presentation of aplastic anemia is at 15 to 25 years or over 60 years. The male-to-female ratio in acquired aplastic anemia is approximately 1:1.

Causal Factors

When no causative factors are ascertained, the cases are classified as idiopathic. A search for possible causative agents is warranted because some patients may improve following the removal of the offending agent. However, most cases of aplastic anemia remain idiopathic. The distinction between acquired versus inherited causes of aplastic anemia is crucial to guide clinical management and treatment (see Chapter 8).

Drugs

The incidence of drug- and chemical-related aplastic anemia[11] varies over time and from place to place. Many drugs and toxins have been implicated by inferential and circumstantial evidence; the magnitude of the risk is usually unknown (Box 6-2). Presence of an agent on this list suggests caution regarding its use, but no drug on this list should be proscribed if there are strong clinical indications for its use. From a public health perspective, even drugs associated with an increased risk of marrow failure do not cause large numbers of cases of aplastic anemia.[3]

Note that even confirmed associations do not substantiate causality. Antibiotics felt to be causative may have been administered for the viral infection that led to the aplastic anemia or for symptoms from already established neutropenia in an undiagnosed case of aplastic anemia. Bleeding may be precipitated in undiagnosed thrombocytopenic patients who receive nonsteroidal antiinflammatory drugs. As an example of known errors in associations, among six patients reported to have sniffed glue and

Box 6-2 **Classification of Drugs and Chemicals Associated with Aplastic Anemia***

AGENTS THAT REGULARLY PRODUCE MARROW DEPRESSION

Antibiotics: daunorubicin, doxorubicin hydrochloride (Adriamycin), chloramphenicol
Antimetabolites: antifolic compounds, nucleotide analogues
Antimitotics: vinblastine, colchicine
Benzene and chemicals containing benzene: carbon tetrachloride, chlorophenols, kerosene, Stoddard solvent
Cytotoxic cancer chemotherapy with alkylating drugs: busulfan, melphalan, cyclophosphamide

AGENTS POSSIBLY ASSOCIATED BUT WITH A LOW PROBABILITY RELATIVE TO USE

Chloramphenicol
Insecticides: chlordane, chlorophenothane (DDT), γ-benzene hexachloride (lindane), parathion
Anticonvulsants: carbamazepine, hydantoins, phenacemide
Nonsteroidal antiinflammatory agents: indomethacin, ibuprofen, oxyphenylbutazone, phenylbutazone, sulindac
Antihistamines: cimetidine, chlorpheniramine, ranitidine
Antiprotozoal drugs: quinacrine, chloroquine
Sulfonamides: some antibiotics, antidiabetics (chlorpropamide, tolbutamide), antithyroid drugs (methimazole, methylthiouracil, propylthiouracil), carbonic anhydrase inhibitors (acetazolamide, methazolamide)
Penicillamine
Metals: gold, arsenic, bismuth, mercury

AGENTS MORE RARELY ASSOCIATED

Allopurinol (may potentiate marrow suppression by cytotoxic drugs)
Antibiotics: flucytosine, mebendazole, methicillin, sulfonamides, streptomycin, tetracycline, trimethoprim/sulfamethoxazole
Carbimazole
Guanidine
Lithium
Methyldopa
Potassium perchlorate
Quinidine
Sedatives and tranquilizers: chlordiazepoxide, chlorpromazine, meprobamate, methyprylon, piperacetazine, prochlorperazine
Thiocyanate

Modified from Young NS, Alter BP: Aplastic anemia: acquired and inherited*, Philadelphia, 1994, WB Saunders, p 104.*

*Agents are listed because they have been cited in the literature; inclusion in this list does not imply acceptance by the author of a causal relationship.

become aplastic, five had sickle cell anemia and aplastic crises now known to be due to parvovirus infection.[12]

The incidence of drug-related aplasia in pediatric cases is low, mainly because many of the drugs felt to be related to aplasia are not used in childhood, with the exception of antiepileptic drugs, carbonic anhydrase inhibitors, nonsteroidal antiinflammatory medications, and some antibiotics.

Drug-related aplasia may occur in several ways. Drugs may exert direct cytotoxic or suppressive effects on the bone marrow. Myelosuppressive drugs, such as those used in cancer chemotherapy, lead to predictable and dose-related marrow suppression. Benzene, too, can be demonstrated regularly to suppress the bone marrow in animals in a dose-linked manner, and most individuals exposed to sufficient amounts of benzene would probably suffer some type of marrow damage. In practice, most drug-related aplastic anemia is idiosyncratic and occurs unpredictably in only rare individuals who are prescribed the medication, sometimes weeks to months after its administration is discontinued. This last category of patients may possess a genetic propensity for this phenomenon or be due to a direct effect of the drug on antigen presentation of abnormal peptides (see below).

Chloramphenicol

Chloramphenicol was considered to be the commonest cause of aplastic anemia at the peak of its use, which began in 1949.[13] A genetic predisposition may exist. The mechanism of the idiosyncratic aplasia remains unknown despite extensive investigation.

Chloramphenicol contains a nitrobenzene ring and thus resembles amidopyrine, a drug known to cause agranulocytosis.[14,15] Chloramphenicol is the prime example of a drug that causes both dose-related marrow suppression through mechanisms that include mitochondrial inhibition,[16] and idiosyncratic aplastic anemia.[17]

The signs of dose-related toxicity appear more rapidly in patients with hepatic or renal disease because the drug must be inactivated by conjugation with glucuronide in the liver and excreted in the urine. High doses and high plasma levels correlate with the characteristic reversible erythroid depression. In vitro, chloramphenicol inhibits the growth of both colony-forming units granulocyte/macrophage (CFU-GMs) and colony-forming units erythroid (CFU-Es)[18,19,20,21,22] and also may inhibit the hematopoietic microenvironment (HM).[20,23]

Other Drugs

Nonsteroidal antiinflammatory drugs, which are used more extensively in adults than in children, are associated with aplasia.[3] Nonsteroidal antiinflammatory drugs associated by occasional case reports with aplastic anemia include aspirin,[24] indomethacin,[25,26,27,28] and ibuprofen.[29] Several large studies reported an increased risk of aplastic anemia with phenylbutazone[30,31] and identified even higher probabilities with some of the other nonsteroidal antiinflammatory drugs.[3] Cimetidine, another commonly used drug, is associated with a 2 per 100,000 user risk of cytopenias.[32,33] Sulfa-containing compounds, which appear as risk factors in most case-control studies of drugs and aplastic anemia, are used in a wide variety of clinical circumstances.[34,35,36,37,38,39,40,41,42,43] Other drugs implicated in aplastic anemia that are commonly used in the pediatric population include anticonvulsants (hydantoins,[44,45,46] carbamazepine[47,48,49,50,51]) and carbonic anhydrase inhibitors[52] (acetazolamide[53,54] and methazolamide[55,56]). Many of the drugs listed in Figure 6-1 also have been associated with agranulocytosis. In general only a minority of cases of aplastic anemia can be assigned a drug association. The distinction between aplasia secondary to the medication versus aplasia arising from the underlying disorder (or occult viral infection) requiring treatment can be difficult.

Chemicals and Toxins

Benzene

Benzene is a particularly dangerous environmental contaminant.[57,58] It is found in organic solvents, coal tar derivatives, and petroleum products.[59,60,61,62] Fatal aplastic anemia, leukemia, or both, have been reported years later in factory workers who had benzene exposure. Benzene is concentrated in bone marrow fat,[63] forms water-soluble intermediates,[64,65,66] and damages DNA.[67,68,69] It decreases the numbers of progenitors and damages stroma. The risk of cytopenias is likely related to cumulative exposure.

Other Aromatic Hydrocarbons

Toxicity thought to be due to other organic solvents may in some instances be caused by benzene contaminants. Neither pure toluene nor xylene is a marrow toxin. Aplastic anemia has been linked by many case reports to insecticides, particularly γ-hexachlorobenzene (lindane) in children.[70] Aromatic hydrocarbons are present in insecticides and herbicides and may comprise the solvents for these agents. Some organophosphate insecticides have been shown to inhibit in vitro hematopoietic colony formation, as has lindane.[71]

Ionizing Radiation

Marrow aplasia may occur as an acute toxic sequela of irradiation due to nuclear bomb explosion, radioactive fallout, reactor accidents, and accidental exposure in medicine and industry. Bone marrow cells may be affected by high-energy γ-rays as well as by ingested or absorbed lower-energy α particles. The radiation injury is to the actively replicating pool of precursor and progenitor cells and also to stem cells, in which DNA damage may have a more severe effect. Nonetheless, radiation-related marrow aplasia is infrequent. Even in a restricted episode, such as the Chernobyl reactor accident in 1986, most immediate deaths were due to skin burns and damage to gastrointestinal and pulmonary systems.

Chronic radiation-induced aplasia is dose related. Patients who were irradiated for ankylosing spondylitis had an increased risk of aplastic anemia, and American radiologists have been reported to have an increased death rate from aplasia (for both groups, the pathologic distinction of aplasia and myelodysplasia was not made). The incidence of late aplasia in atomic bomb victims was not increased, nor was it increased in patients receiving radiation therapy for malignancies. Knospe and co-workers suggested that irradiation with an exposure greater than 4.4 Gy was required for the development of aplasia; they also postulated that low doses might damage only stem cells, whereas high doses would also damage the supportive hematopoietic stromal microenvironment.[72]

Infectious Agents

Patients with bacterial or viral illnesses frequently develop mild pancytopenia during or following the infection (see Chapter 37). Patients with bacterial or viral infections often receive antibiotics and other medications, and it is frequently not clear whether an ensuing aplastic anemia was caused by the infection, by the drug, or by the combination of the two, or even whether the infectious illness was the result and not the cause of the pancytopenia.

Hepatitis

Although hepatitis is frequently associated with mild depression of blood cell counts, aplasia is a rare sequela, estimated to occur in fewer than 0.07% of the total number of pediatric hepatitis cases[73] and in fewer than 2% of those with non-A, non-B hepatitis.[74] Nonetheless as an identifiable clinical event, a prior episode of hepatitis is recognized in 2% to 5% of aplastic anemia patients in a Western series.[75] The prevalence of prior hepatitis is about twofold this proportion in the Far East.[76] Among children with aplastic anemia in Taiwan, 24% had a history of recent acute hepatitis.[77] Antecedent hepatitis may be subclinical, as about 50% of patients with aplastic anemia may have elevated hepatic transaminases before their first transfusion. In a report of 32 patients with liver transplantation for hepatic failure following non-A, non-B hepatitis, 28% developed aplastic anemia.[78] While aplasia has been reported following both hepatitis A and B virus infections,[79, 80] the majority of cases of the hepatitis/aplasia syndrome are not associated with serotypable hepatitis virus.[81, 82]

A study of aplastic anemia patients reported to the European Registry from 1990-2007 found that 5% of patients with aplastic anemia had an antecedent seronegative hepatitis. Hepatitis-associated aplastic anemia was slightly more common in males and tended to present at a younger age. Actuarial survival after treatment with either immunosuppression or hematopoietic stem cell transplant was similar between patients with hepatitis-associated aplastic anemia versus other acquired aplastic anemia.[83]

Flaviviruses

Flaviviruses cause arbovirus hemorrhagic fevers, dengue, and other hematodepressive syndromes. Dengue can propagate in bone marrow cultures without direct cytotoxicity, and dengue antigens induce lymphocyte activation and the release of marrow suppressive cytokines.[84]

Epstein-Barr Virus

Herpesviruses such as Epstein-Barr virus (EBV) are large, complex DNA viruses.[85] EBV causes infectious mononucleosis, which has pancytopenic complications in less than 1% of cases. More than 12 such cases have been reported, and one half of these cases had a fatal outcome. In one study, EBV was demonstrated by immunologic and molecular methods in the bone marrow of six patients with aplastic anemia.[86] Only two had a history of typical mononucleosis, although all six had serologic evidence, suggesting that EBV may be an unrecognized cause of aplastic anemia. The EBV's target is B cells, although T cells also may be infected. Because EBV is a common infection, issues of ascertainment can render the causative determination of aplasia difficult.

Cytomegalovirus and Human Herpesvirus 6

Infection with cytomegalovirus (CMV) may lead to graft failure in immunosuppressed bone marrow transplant (BMT) recipients.[87] CMV can infect marrow stromal cells in vitro and can inhibit their ability to produce growth factors;[88] direct progenitor cell infection by some CMV strains also has been documented.[88,89] Herpesvirus 6 is the cause of exanthem subitum[90] and, like CMV, may be found in the marrow of patients with graft failure after transplantation,[91] as well as in hematopoietic progenitors infected in vitro.[92] As with other viruses, both of these are ubiquitous infections making causality difficult to ascertain.

Human Immunodeficiency Virus

Patients with acquired immunodeficiency syndrome (AIDS) often have cytopenias,[93] but their marrow is much more commonly cellular and dysplastic than empty. Colony formation by marrow from patients may be diminished.[94,95,96,97] The action of human immunodeficiency virus-1 (HIV-1), a lentivirus, on hematopoietic cells remains a subject of controversy. HIV-1 infection of CD34+ cells has been difficult to detect in vivo from patient material[96,98] or after tissue culture infection of normal cells.[96,99] The virus apparently directly infects megakaryocytes, which bear the CD4 receptor present on T cells.[100] The virus also may affect stroma functions, at least in vitro.[101,102] HIV-1 can act indirectly on hematopoiesis through inhibitory lymphokine production: The envelope glycoprotein can stimulate macrophages to produce tumor necrosis factor (TNF), which in turn inhibits hematopoietic colony formation.[103] Hematologic suppression can also be due to opportunistic infections, neoplasms, or marrow suppression from the drugs used to treat AIDS and its complications.

Other Viruses

Blood count abnormalities, which are rarely severe, may be observed in the course of rubella, measles, mumps, varicella, and influenza A.[104]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a disease characterized by variable combinations of mild to severe intravascular hemolysis, large venous thromboses, and aplastic anemia.[105] It is uncommon in adults and even rarer in children (see Chapter 13). There is a clear association of PNH with aplastic anemia: Many patients with PNH develop pancytopenia and marrow hypoplasia, and PNH clones are detectable in up to 50% to 70% of patients with acquired aplastic anemia.[106,107,108,109]

PNH is characterized by an inability to inactivate complement on the erythrocyte cell surface, resulting in increased sensitivity to complement. Deficits were subsequently identified in a family of membrane proteins, all of which were anchored to the cell membrane via glycosylphosphatidylinositol (GPI). GPI binds covalently to specific carboxyl terminal protein sequences and attaches them to cell membrane phosphatidylinositol residues. The genetic defect in PNH was localized to the X-linked phosphatidylinositol glycan class A (PIG-A) gene, whose product functions in the transfer of N-acetylglucosamine to phosphatidylinositol as an early step in GPI anchor formation. Early tests for PNH, such as the Ham test or sucrose hemolysis test, relied on the demonstration of increased sensitivity to complement-mediated red cell lysis. Increased sensitivity and specificity are achieved using flow cytometry assays for the absence of GPI-anchored proteins such as CD59 and CD55.[110] More sensitive tests utilize aerolysin, a channel-forming toxin that binds GPI-anchored proteins to result in cell lysis but leaves the GPI-deficient PNH cells intact.[111] The use of a fluorescently labeled aerolysin variant that binds to GPI but fails to lyse the cells offers increased sensitivity and specificity for the detection of the PNH clone.[112]

The clinical significance of small populations of PNH clones is unclear, and most of the published data are derived from adult patients. Small numbers of PNH cells are detectable in healthy controls,[113] although the PNH cells in this context are typically polyclonal. Despite the frequent finding of PNH clones in the bone marrows of aplastic anemia patients, only 10% to 15% of patients subsequently develop the clinical syndrome of PNH.[114] In the majority of patients, such clones may persist or disappear; however, some patients may develop large symptomatic PNH clones requiring therapeutic intervention.[115,116] Patients with small asymptomatic PNH clones may respond to the same treatments as other patients with aplastic anemia. Patients who develop large PNH clones are at risk for developing symptoms of hemolysis or thrombosis.[115] One recent retrospective study included 47 pediatric patients with aplastic anemia of whom 14 had a PNH clone greater than 1% at baseline (median clone size 16%). The median clone size remained small for all patients, and none of these patients developed clinical symptoms of PNH.[115]

The etiology of marrow aplasia in PNH remains an area of active investigation. Although severe combined immunodeficiency (SCID) mice infused with bone marrow from PNH patients show preferential engraftment with the PNH clones,[117] studies of hematopoiesis in PNH patients have not detected any selective proliferative advantage of the *PIG-A*$^-$ hematopoietic clones.[118] A subsequent study comparing in vitro proliferation of *PIG-A*$^-$ and *PIG-A*$^+$ CD34 cells from PNH patients found a selective growth deficiency in the *PIG-A*$^+$ cell population rather than an advantage for the *PIG-A* mutant cells: Fas expression was elevated on the wild type compared with the GPI-deficient cells, suggesting increased resistance to apoptosis as one potential mechanism to explain their findings.[119] No proliferative advantage of PNH hematopoietic clones was observed in mice mosaic for the *PIG-A* gene.[120,121] To evaluate the hypothesis that autoreactive T cells might preferentially eliminate *PIG-A*$^+$ hematopoietic stem cells while sparing the PNH clones, the sensitivity of normal versus PNH EBV-transformed B-cell lines to autologous EBV-specific T-cell lines was examined.[122] The PNH cells were no less sensitive to T-cell-mediated cytotoxicity than the non-PNH cells; thus the GPI-linked cell surface molecules are not required for killing by T cells. An abnormal distribution of expanded T-cell clones detected by size analysis of the complementarity-determining region 3 (CDR3) in the β-variable region (BV) mRNA of the T-cell receptor (TCR) has been noted in PNH patients,[123] although the targets of such T-cell populations remain to be ascertained. The mechanisms underlying the clonal expansion of the GPI-negative cells in PNH or aplastic anemia is currently unclear.[124] Despite the presence of clonal populations of PNH cells, patients with PNH do not exhibit an increased incidence of leukemias, and the GPI-negative clones do not behave in a malignant fashion.

Immunologic Diseases

Ten percent of patients with the rare collagen vascular syndrome, *eosinophilic fasciitis,* have associated aplastic anemia.[125] This condition is usually limited to adults. Thymoma associated with hematopoietic failure generally but not exclusively presents as pure red cell aplasia.[126] Some of the adult cases had also received drugs such as chloramphenicol or sulfonamides, and the aplasia could have been due to the drugs alone or to the combination. An iatrogenic aplasia can be induced by the transfusion of competent lymphocytes into immunodeficient hosts. In these cases, marrow failure arises from the transfusional graft-versus-host disease (GVHD).[127]

Pathophysiology

The purported mechanisms for failure of hematopoiesis are predicated on our current knowledge of normal hematopoiesis (see Chapter 7). Disease could result from decreased numbers or defective function of the cellular or soluble components required for blood cell production or from exogenous factors that result in damage or elimination of hematopoietic cells. Figure 6-2 depicts different potential mechanisms for the loss of hematopoietic cells in aplastic anemia. In model I, marrow toxins such as irradiation, drugs, or chemicals or direct invasion by viruses might cause hematopoietic stem and/or progenitor cell death. In model II, an underlying abnormality of the hematopoietic cells may result in a predisposition to hematopoietic stem cell damage, premature stem cell loss, or insufficient stem cell production (see Chapter 1). In model III, viruses, drugs, toxins, or immune dysregulation may incite a cellular or humoral immunologic reaction against a normal hematopoietic compartment. In model IV, abnormalities of the marrow stromal environment may actively inhibit hematopoiesis. These possibilities are not mutually exclusive, and supportive data for each model have been described. Current data suggest that aplastic anemia may represent the final seemingly common outcome of different pathogenic mechanisms, with different underlying causes entailing different medical management considerations.

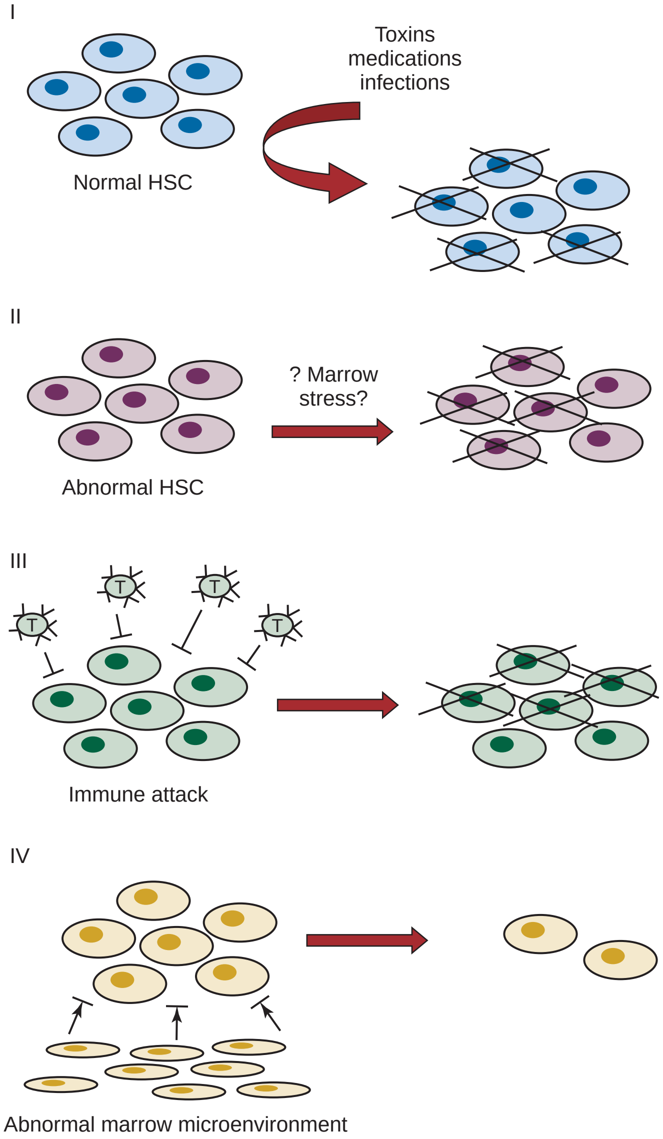

Figure 6-2 Models for the pathogenesis of aplastic anemia. I. Healthy hematopoietic stem cells and progenitors are damaged by exogenous agents such as toxins, medications, or infectious pathogens resulting in marrow aplasia. II. Abnormal marrow cells (e.g., inherited marrow failure syndromes) undergo premature attrition. Marrow aplasia might be exacerbated by external factors. III. Immune-mediated attack (cellular or humeral) eliminates hematopoietic stem cells and progenitors. IV. Abnormal marrow microenvironment impairs hematopoiesis. *HSC,* Hematopoietic stem cell.

Hematopoietic Stem Cells and Clonality

Patients with aplastic anemia have decreased numbers of blood and marrow committed progenitor cells, assayed as myeloid colony-forming cells (CFU-GMs); erythroid colony-forming cells (CFU-Es and burst-forming units erthyroid [BFU-Es]); megakaryocytic progenitors (CFU-megas); multipotent colony-forming cells (CFU granulocyte, erythrocyte, monocyte, megakaryocyte [CFU-GEMMs]); and *long-term culture-initiating cells* (LTC-ICs).[128,129] Hematopoietic cells can also be assessed phenotypically for the presence of the CD34 antigen, which defines a compartment of about 1% of marrow cells that includes progenitors and possibly activated stem cells.[130,131,132,133] CD34+ cells are reduced in aplastic anemia, and almost all patients show not only severe reduction in the numbers of these cells but also poor plating efficiency for colony formation from purified CD34+ cells.[134,135]

Several lines of evidence point to primary abnormalities in the hematopoietic stem cell as a potential etiology for aplastic anemia. Multiple studies have noted that simple infusion of stem cells from an identical twin donor without prior conditioning was sufficient to treat the aplasia in many cases.[136,137,138,139] These results strongly support a pathogenic stem cell defect and argue against permanent disorders of the bone marrow environment, including immunologic mechanisms, as the cause of stem cell destruction. Low stem cell numbers persist even with hematologic recovery after medical therapy with antithymocyte globulin (ATG) and cyclosporine (see following discussion), and blood cell parameters, such as macrocytosis, do not return to normal in many cases, again suggestive of an underlying stem cell abnormality. A primary stem cell defect likely also contributes to the observation of clonal hematopoiesis in aplastic anemia[140] as well as late development of other hematologic diseases such as myelodysplasia and acute leukemia (see following discussion).

A subset of patients with seemingly idiopathic aplastic anemia may actually carry an inherited/congenital predisposition to marrow failure (see Chapter 7). Although the inherited/congenital marrow failure syndromes are often associated with characteristic physical findings, patients may present with isolated aplastic anemia as the sole manifestation of their underlying inherited syndrome.[141] In some patients lacking significant physical findings or cytopenias at the time of evaluation, an elevated mean corpuscular volume (MCV) may be the only clue to an underlying inherited marrow failure syndrome. A careful family history for hematologic abnormalities, malignancy predisposition, or other characteristic clinical stigmata may be helpful in distinguishing an inherited marrow failure syndrome.[142] For example a subset of patients presenting with aplastic anemia without other clinical stigmata of an inherited marrow failure syndrome were found to harbor mutations in the dyskeratosis congenita genes *hTERC,*[143,144] which encodes the RNA component of telomerase, or hTERT,[145,146,147] which encodes the catalytic subunit of the telomerase complex. Telomeres are specialized structures that stabilize the ends of each chromosome to prevent excessive shortening with replication, to distinguish chromosome ends from internal DNA breaks, and to prevent end-to-end fusions. Telomeres consist of six–base pair repeated sequences (TTAGGG) associated with a specific protein complex. Telomerase is a ribonucleoprotein enzyme consisting of an H/ACA RNA component (TERC) complexed with a reverse transcriptase (TERT) and additional H/ACA binding proteins including dyskerin, GAR1, NHP2, and NOP10. When telomerase levels are diminished or absent, telomeres progressively shorten with each cell division. At a critically short telomere length, a checkpoint is triggered for cells to stop dividing and undergo senescence to prevent chromosomal rearrangements.

Shortened telomeres have been observed in the leukocytes of aplastic anemia patients.[148] Of five patients noted to have mean telomere lengths less than 5 kb, three had acquired cytogenetic abnormalities, suggesting that compromise in the telomere's probable role in stabilizing chromosome ends may contribute to the increased incidence of myelodysplasias and acute leukemias. A study by Brummendorf and colleagues reported relatively normal telomere lengths in patients who responded to immunosuppression, while untreated or unresponsive patients showed significant telomere shortening.[149] Telomere shortening is a common feature associated with marrow failure, though telomere lengths are particularly short in patients with dyskeratosis congenita, a disorder of telomerase function, even in comparison to other marrow failure patients.[150] Whether telomere shortening in marrow failure patients lacking telomerase mutations represents a primary defect in telomere maintenance or a secondary effect of increased cycling of the few remaining hematopoietic stem cells remains to be clarified. Shorter telomere lengths have been associated with a higher risk of relapse and clonal progression with decreased survival in patients with aplastic anemia.[151]

Immune Destruction

Several lines of data suggest that immune phenomena may result in aplastic anemia.[152] In some syngeneic (identical twin) BMTs, simple infusion of stem cells is not sufficient to reconstitute hematopoiesis. The requirement for prior conditioning of the host may reflect some operational immunologic process, though it is also consistent with the presence of an underlying clonal abnormality that requires ablation.[153] Histocompatibility studies conducted in Europe, Asia, and America have indicated an increased representation of HLA-DR2 among aplastic anemia patients, consistent with a genetically determined immune susceptibility to disease.[153,154,155] Evidence for specific immune mechanisms is reviewed below.

Lymphocytes

Lymphocyte infusions in mouse models result in marrow destruction and aplastic anemia.[156] Autologous recovery has been reported after either mismatched or matched transplants in patients prepared with antilymphocyte sera or cyclophosphamide.[157,158,159] While the etiology of aplastic anemia in children remains unclear, evidence supports an immunologic mechanism of disease in the absence of known environmental toxins, drugs, and constitutional syndromes. Overriding these considerations are the large proportion of responses in acquired aplastic anemia to immunosuppressive therapies, although the antilymphocyte preparations contain heterogeneous mixtures of antibodies to many cells, including lymphocytes, and are clearly immunosuppressive as well as generally cytotoxic. Cyclosporine exerts inhibitory T cells effects and inhibits transcription of genes for cytokines including IL-2 and interferon-gamma (IFN-γ).[160] It has many other toxic effects on several tissues, including brain and kidney. The diverse antibodies in ATG react with a wide range of antigens, including signal transduction and adhesion molecules.[161] Thus the attribution of immune dysregulation as causal in aplastic anemia based on therapy must be tempered with caution because ATG and cyclosporine exert multiple effects in addition to immunosuppression. Of note, therapies with mixtures of monoclonal antibodies specific for human T cells have not been effective in clinical trials to date[162] (see following discussion). Furthermore ATG can increase colony growth in normal, myelodysplastic syndrome (MDS), and aplastic anemia CD34+ bone marrow cells in culture.[163,164] ATG treatment also reduces the expression of Fas-Ag on aplastic anemia bone marrow CD34+ cells.[165] Effective treatment of myelodysplasia with immunosuppressive medications has been reported[166] and may suggest that such agents might exert additional effects on the bone marrow.[167]

Nonetheless multiple reports have demonstrated an association of aplastic anemia with alterations in lymphocyte numbers or specific immunologic changes at presentation and in some cases further changes with hematologic responses. Hoffman and colleagues showed inhibition of erythroid growth in vitro utilizing coculture of peripheral blood lymphocytes from five out of seven aplastic anemia patients studied. [168] Zoumbos and colleagues noted increased circulating and bone marrow levels of IFN-γ in aplastic anemia patients and a response of increased colony growth in vitro in response to inhibition with neutralizing antibody to this proinflammatory cytokine.[169] Hinterberger and colleagues failed to confirm the reported increased circulating levels of proinflammatory cytokines in aplastic anemia patients, but did demonstrate increased TNF and IFN-γ production by peripheral blood mononuclear cells (PBMCs) from aplastic anemia patients at baseline and after stimulation in vitro.[170] Risitano and colleagues reported a dominant clonal T-cell immune response characterized by flow cytometry using antibodies against different TCR-β subfamilies and by sequencing the CDR3 region of the TCR-β chain in 54 patients studied with aplastic anemia.[171] The size of these clones and the total number of T cells decreased following successful treatment with ATG and increased with relapse. This phenomenon was associated with HLA-DR1501 genotype and activated cytotoxic T cells assayed in vitro. The association with HLA type was not confirmed by a subsequent study of Japanese patients.[172] Solomou and colleagues reported reduced T regulatory cells (TRegs) (CD4+, CD25+, FoxP3$^+$) in 20 patients with aplastic anemia that was consistent with increased IFN-γ and a TH1 polarization phenotype of T cells.[173] Six of seven patents showed slightly increased numbers of TRegs after immunosuppression therapy (IST) during hematologic responses. In a case report, Ikeda and colleagues noted marked alteration of the CD4/CD8 T-cell ratio after hepatitis that was subsequently followed by onset of aplastic anemia.[174] IST was followed by normalization of lymphocyte subsets with hematologic recovery.

These studies imply concomitant immune dysregulation with aplastic anemia and suggest a mechanism by which IST could be working therapeutically. However, no specific antigen has previously been implicated mechanistically in the evolution of aplasia. In a recent report, it was shown that a prodrug of the anti-HIV drug, abacavir, which is associated with a hypersensitivity reaction in treated patients, can bind to the HLA-B*57:01 molecule, resulting in altered peptide presentation.[175] The altered peptides appear as foreign and lead to activation of CD8+ T cells. One can imagine such a scenario leading to acquired aplastic anemia if the abnormal peptide presentation of "self-antigens" leads to CD8 activation directed against hematopoietic stem cells in the bone marrow. While such a finding is not reported yet in aplastic anemia patients, this could underlie the immunologic mechanism long hypothesized as the etiology of this disease. Interestingly Weinstock and colleagues also recently demonstrated somatic alterations in 20% of adult patients with acquired aplastic anemia utilizing next generation sequencing technology.[176] Alterations included mutations of *DNMT3A* and *ASCL1,* both associated with MDS in adults, and mutations of β_2-microglobulin, which is required for class I expression and CD8 T-cell function. Thus previously unrecognized mutations may predispose to acquired aplastic anemia via either mechanisms leading to a prodrome of myelodysplasia or by subtle alternations in immune functions. Limitations of these studies include the paucity of purified cell populations required for sequencing and the lack of functional data that addresses the biologic relevance of these alterations with respect to stem cell function and hematopoiesis. Additional studies will undoubtedly follow.

Lymphokines

Whether overproduction or dysregulated production of inhibitory cytokines represents a primary etiology versus a secondary effect of an underlying bone marrow abnormality remains unclear. IFN-γ, a soluble inhibitor produced by T cells, was found to be produced at high levels in cultures from aplastic anemia patients.[177,178,169] IFN-γ is expressed in the marrow of most patients with aplastic anemia but not in normal people or in patients with other hematologic diseases who have undergone frequent transfusions.[179,180] High pretreatment intracellular γ-interferon levels correlated with response to immunosuppressive therapy.[181] Other inhibitory cytokines, such as *TNF*[182] and *macrophage inflammatory protein-1,*[183,184] also are overexpressed in aplastic marrow. Both interferon and TNF directly and synergistically inhibit hematopoiesis in vitro.[185] In long-term bone marrow culture, constitutive low-level expression of IFN-γ is sufficient to markedly reduce the output of committed progenitor cells and LTC-ICs, the stem cell surrogate.[186] Both interferon and TNF increase the potential for programmed cell death within the CD34+ compartment by increasing Fas antigen expression on target cells.[187] Fas antigen is a cell surface molecule in the TNF receptor family; its activation signals apoptosis.

Microenvironment

In theory aplastic anemia could be due to a microenvironment that fails to support hematopoiesis: a lesion of "soil" rather than "seed."[72] The role of the HM in etiology of aplastic anemia or the response to treatment remains controversial. Ershler and colleagues showed decreased erythroid growth in whole bone explants from a single patient with constitutional red cell aplasia but no effect from the patient's plasma, mononuclear cells, or T cells, implying an HM defect.[188] This observation is reminiscent of the HM defect seen in *Steel* mice,[189] which lack production of normal stem cell factor (SCF) in nonhematopoietic cells, but it seems more likely that this was simply a demonstration of a cell-intrinsic erythroid cell defect. Dexter and colleagues described an in vitro long-term marrow culture (LTMC) that consisted of an adherent cell compartment made up of a number of different cell types that supported hematopoiesis for weeks to months ex vivo.[190] Subsequently Marsh and colleagues examined LTMC from 32 adult aplastic anemia patients and found 31 of the 32 had abnormal hematopoiesis in these cultures.[191] However, using cross-over cultures, only 1 of 23 patients had defective adherent components. Juneja and colleagues demonstrated reduced cobblestone areas (containing active hematopoiesis) but normal adherent cell fractions in eight aplastic anemia patients compared with normal controls.[192] Marsh and colleagues utilized human LTMC and assessed the HM in cross-over experiments.[193] They demonstrated that stroma generated from aplastic anemia patients performed normally when inoculated with CD34+ cells from normal donors. Nissen and colleagues compared short-term stroma and progenitor colony growth in aplastic anemia patients treated with or without IST and found a modest increase in both of these cell fractions in treated versus untreated patients.[194] Chatterejee and colleagues used a cytotoxic drug animal model of aplasia to demonstrate failure of recovery of marrow stromal cells with time.[195] While this study may be relevant to some isolated instances of acquired aplastic anemia, it seems more relevant to marrow damage in cancer or leukemia patients undergoing therapy. Shipounova and colleagues showed impaired adipogenesis and osteogenic potential with increased size and number of fibroblast colonies from aplastic anemia patients' bone marrow.[196] These authors also demonstrated increased stromal-derived cytokines, including ANG1, VEGF, and VCAM-1. Overall these studies suggest some alterations in the HM of aplastic anemia patients, but there is currently no definitive evidence in humans of a mechanistic link between defective marrow microenvironment and development of acquired aplastic anemia.

More recently interest has focused on defining specific anatomic and/or biochemical spaces (niches) in the bone marrow occupied by hematopoietic stem cells. Schofield first termed the phrase *stem cell niche* to define a supporting cellular environment in which hematopoietic stem cells reside.[197] Currently controversy exists about the overall relevance of the two best-studied stem cell niches.[198] Hematopoietic stem cells appear to reside in close proximity to osteoblasts that line the cortical bone of the marrow space, and osteoblasts may be important in maintaining quiescence of the primitive hematopoietic stem cells. This area of the marrow has thus been termed the *osteoblastic niche*. A subset of these cells, spindle-shaped N-cadherin$^+$ CD45$^-$ osteoblasts (SNO cells) residing in trabecular bone, may be derived from mesenchymal stem cells, and their number correlate with the content of long-term hematopoietic stem cells.[199] Ablation of osteoblasts leads to loss of HSC[200] and failure of hematopoiesis, while manipulations that increase osteoblasts have the opposite effect.[201]

An anatomically distinct putative hematopoietic stem cell niche is made up in part by sinusoidal endothelial cells and has been termed the *perivascular niche*.[202] Some data suggest this niche may be critical for mobilization and homing of hematopoietic stem cells via the Rac GTPase pathway[203,204] and/or for progenitor cell proliferation and differentiation,[205,206] although these studies have not examined long-term hematopoietic stem cells in functional assays. Alterations of the sinusoidal endothelium with antibodies to VE-cadherin leads to failure of megakaryocytopoiesis in murine models.[205] Some models suggest that quiescent hematopoietic stem cells may migrate from the osteoblastic niche to the perivascular niche via β1 integrin function and chemokine/growth factor stimulation. Overall, whether there are truly distinct functional differences between these putative hematopoietic stem cell niches remains to be determined, and the role of specific growth factors, adhesion molecules, and chemokines are incompletely understood. A long-term goal of investigators in this field is to recapitulate the HM in vitro such that true expansion of hematopoietic stem cells may occur in the laboratory setting. Success in this area would have a major impact in BMT and regenerative medicine.

Hematopoietic growth factor production and plasma levels are usually increased rather than decreased in patients with aplastic anemia.[207] Circulating levels of erythropoietin, granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF), thrombopoietin, and flt-3 ligand are elevated in patients with aplastic anemia. SCF levels have been reported to be low to normal. Levels of interleukin 1 (IL-1), produced by monocytes, may be low in aplastic anemia. Therapeutic trials with these factors have yielded divergent and incomplete responses,[208] casting doubt on the pathophysiologic significance of deficiency of these factors. The report of inhibitory effects of marrow adipocytes on hematopoiesis in mouse models is intriguing given the typical fatty replacement observed in aplastic bone marrows.[209]

Clinical Evaluation

The differential diagnosis of pancytopenia is broad (Box 6-3). The evaluation and diagnostic work up of the patient with presumed acquired aplastic anemia should be directed at eliminating alternative diagnoses for which curative therapies are available or for which the therapies for aplastic anemia would be inappropriate (Table 6-1). Because the inherited marrow failure syndromes entail different medical management issues, a careful medical history, family history, physical examination, and appropriate laboratory evaluation to assess for underlying inherited bone marrow failure syndromes should be pursued. The diagnosis of an inherited marrow failure syndrome also carries profound implications for hematopoietic stem cell donor selection from family members and may be important for family planning. Given the wide clinical variability of the inherited marrow failure syndromes even amongst members of a given family, all siblings of a patient with an inherited marrow failure disorder should be tested whether or not they appear to carry clinical stigmata of the disease.

History

The chief presenting symptoms relate to low blood counts. Bleeding, such as gum oozing, nosebleeds, easy bruising with minimal trauma, or heavy menses may be seen. Chronic anemia may present with fatigue, decreased

Box 6-3 Causes of Pancytopenia

HYPOCELLULAR BONE MARROW

Acquired aplastic anemia
Inherited bone marrow failure syndrome
(Fanconi anemia, amegakaryocytic thrombocytopenia, dyskeratosis congenita, Shwachman–Diamond syndrome, GATA-2 syndromes)
Paroxysmal nocturnal hemoglobinuria*
Hypoplastic myelodysplastic syndrome
Virus-associated aplastic anemia

CELLULAR BONE MARROW

PRIMARY BONE MARROW DISEASE

Myelodysplasia
Paroxysmal nocturnal hemoglobinuria*

SECONDARY TO SYSTEMIC DISEASE

Systemic lupus erythematosis, Sjögren syndrome
Hypersplenism
Vitamin B_{12}, folate deficiency
Infection
Storage disease (Gaucher, Niemann-Pick)
Alcoholism
Sarcoidosis
Infiltrative bone marrow disorders
Acute myelogenous leukemia
Acute lymphoblastic leukemia
Hemophagocytic lymphohistiocytosis
Metastatic solid tumors
Osteopetrosis
Myelofibrosis

activity, or exercise intolerance, though the gradual onset of severe anemia can be surprisingly well compensated in young children. Serious infection is not a frequent presenting symptom early in the course of aplastic anemia. Many patients feel well with few symptoms on initial presentation. A history of steatorrhea or fatty food intolerance may be a manifestation of Shwachman–Diamond syndrome, though the absence of these symptoms does not rule out this diagnosis.[210] Gastrointestinal disorders may also be associated with other inherited marrow failures syndromes such as dyskeratosis congenita or Fanconi anemia. A careful family history for blood disorders, malignancies (particularly ovarian and breast cancer or hepatocellular carcinoma), premature graying, hepatitis, pulmonary fibrosis, or congenital anomalies that might suggest an inherited bone marrow syndrome should be sought. Patients with a history suggestive of a familial marrow failure syndrome or familial MDS should be evaluated further with genetic and laboratory studies. A developmental history can provide a helpful screen for potential congenital, metabolic, or storage diseases. A detailed medication, environmental, and infectious history, particularly for the period 1 to 12 months prior to presentation, should be obtained.

Physical Examination

Clinical appearance is related to the severity and duration of the underlying pancytopenia. Hemorrhagic manifestations from thrombocytopenia occur early and include petechiae (particularly on the border of the hard and soft palate), ecchymoses, epistaxis, and bleeding from mucous membranes. Neutropenia may be associated with oral ulcerations, bacterial infections, and fever; these signs are rarely present early. Evidence of erythropoietic failure characterized by pallor, fatigue, and tachycardia is often late because the life span of the erythrocyte (120 days) far exceeds that of platelets (10 days) or white cells (variable, but measured in hours for granulocytes). Mucous membranes and nail beds may be pale. Lymphadenopathy, splenomegaly, and severe weight loss are uncommon and may suggest other underlying disorders. Short stature, congenital anomalies (particularly of the thumbs and forearms), areas of hyper- or hypopigmentation, dystrophic nails, immunologic abnormalities, or pulmonary disease should alert the examiner to possible inherited bone marrow failure disorders. Immunologic abnormalities or lymphedema raises consideration of inherited GATA-2 syndromes (see Chapter 24).

Laboratory Studies

Evaluation should include a complete blood count and reticulocyte count. A careful evaluation of the peripheral blood smear may suggest infection or dietary deficiency. Blood counts are most often uniformly depressed. The blood smear shows a paucity of platelets and leukocytes. The anemia is often macrocytic and particularly useful in pointing to a possible constitutional syndrome, though if erythropoiesis is entirely arrested, it may be normocytic. The red cell distribution width (RDW), a numeric measure of anisocytosis, is most often normal. Platelet size is not increased, as it is in most cases of immune thrombocytopenias. The absolute reticulocyte count is decreased. Granulocyte numbers are clearly diminished, as may be those of monocytes and lymphocytes.[211,212] Increases in fetal hemoglobin (Hb F) and red cell *i* antigen are manifestations of the fetal-like erythropoiesis seen in stress hematopoiesis[213] but occur irregularly in aplastic anemia patients, have no prognostic value, and can persist in recovered patients.

Laboratory evaluation for possible infectious etiologies should be obtained as clinically indicated. Additional testing for possible immunologic or autoimmune diseases may be considered. Blood tests to rule out Fanconi anemia and PNH are important, as these diagnoses would entail alternative treatments. Telomere length measurements may be useful as a screen for possible underlying telomere disorders. Very short telomeres in long-lived lymphocyte populations should prompt consideration of additional genetic workup for dyskeratosis congenita. Data on the use of telomere measurements in isolation to guide clinical treatment decisions in this setting are sparse. A growing array of genetic testing is available to assist in the diagnosis of many of the inherited marrow failure syndromes (see Chapter 7). Patients with stigmata of collagen vascular disease should be appropriately evaluated. Early HLA typing of the patient and family members is helpful in guiding future therapies. Baseline renal and hepatic laboratory evaluations are also indicated prior to the initiation of potentially nephrotoxic or hepatotoxic therapies.

Bone marrow examination must be done by both aspiration and biopsy so that cellularity can be evaluated

TABLE 6-1 Clinical Evaluation[340]

Clinical History	**Rationale**
Recent illnesses	Infectious etiology
Medications	Marrow suppression
Toxic exposures	Marrow suppression
Family history of blood disorders, malignancy, congenital anomalies	Assess for inherited marrow failure
Physical Examination	
Vital signs	Clinical sequelae of cytopenias
Height and weight	Assess for inherited marrow failure
Congenital anomalies, stigmata	Assess for inherited marrow failure Assess for other systemic diseases
Laboratory Tests	
Complete blood count and differential	Defines severity
Morphology	Malignant versus benign Vitamin B_{12} deficiency Storage disease
Reticulocyte count	Defines severity Differentiate production versus destruction
Bone marrow biopsy	Assess cellularity Assess architecture (granuloma, fibrosis, hemophagocytosis, infiltrative or metastatic disease)
Bone marrow aspirate	
Morphology	Malignant versus benign Storage disease Hemophagocytosis Congenital disorder
Cytogenetics	Myelodysplasia
Culture	Infectious agent (e.g., tuberculosis, virus)
Other	DNA/antigen-based viral tests
Peripheral blood	
Chemistry	
AST, ALT, GGT, Bilirubin, LDH	Hepatitis
Coombs test	Autoimmune cytopenias
BUN, creatinine, electrolytes	Chronic renal failure
Serologic testing/PCR	Hepatitis, EBV, HIV, other virus
Flow cytometry for CD55/CD59	Paroxysmal nocturnal hemoglobinura
Diepoxybutane or mitomycin C chromosomal breakage	Fanconi anemia
Telomere length, dyskeratosis congenita	
Autoimmune disease evaluation	Evidence of collagen vascular disease
Histocompatibility testing of patient and family	Establish potential donor pool

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *BUN*, blood urea nitrogen; *GGT*, γ-glutamyl transferase; *LDH*, lactate dehydrogenase.

both qualitatively and quantitatively. The bone marrow in aplastic anemia is hypocellular, with empty spicules, and increased fat, reticulum cells, plasma cells, and mast cells. In young children there may be residual lymphocytes that appear prominent due to the lack of myeloid elements in the marrow cavity. Some dyserythropoiesis, with megaloblastosis and nuclear-cytoplasmic asynchrony, may be seen. Aspirates alone may appear hypocellular owing to dilution with peripheral blood, or they may look hypercellular because of areas of focal residual hematopoiesis. Biopsies provide more reliable specimens for assessment of cellularity. Biopsies also provide critical information regarding bone marrow architecture such as fibrosis or granulomas. Bone marrow aspirates should also be sent for karyotype analysis and fluorescence in situ hybridization (FISH) to assess for clonal cytogenetic abnormalities associated with myelodysplasia or malignancy. While FISH studies are more sensitive, they can only detect the specific chromosomal abnormality tested. Bone marrow may also be sent for culture or DNA-based antigen detection of infectious agents such as viruses, though interpretation is tempered by the frequent persistence of viral DNA long after the active infection has passed.

Management and Outcome

Prognosis

Outcome depends on the types of treatments offered, the causes of the aplasias, and the eras and countries being analyzed. In a large series conducted before 1957, Wolff found a survival rate of only 3%.[214] In other series ending no later than 1965, complete recoveries were reported in 10% to 35% of patients. In a series of 40 pediatric patients seen before 1958, Shahidi and Diamond found that only two patients recovered, one of whom later had recurrence,[215] though these studies may have included patients with moderate disease for whom spontaneous recovery is more common.[216,217] Long-term prognosis is adversely affected by delayed complications such as clonal disease. The clinical course of 24 pediatric patients with moderate aplastic anemia was followed for a median of 66 months (range 10 to 293 months).[218] Moderate aplastic anemia was defined as marrow hypoplasia of less than 50%, at least two cytopenias such as an absolute neutrophil count (ANC) less than 1500/mm^3, platelet count less than 100,000/mm^3, or reticulocytopenic anemia lasting at least 6 weeks. Sixteen patients (67%) progressed to severe aplastic anemia, five patients (21%) remained in the moderate range, and three patients (12%) resolved. It is currently unclear whether early institution of therapy for moderate aplastic anemia confers improved outcome. Because current therapies are associated with significant side effects, their institution for children with moderate aplastic anemia, for whom the marrow aplasia may spontaneously resolve, warrants careful consideration.

Spontaneous Recovery

Spontaneous recovery has been reported anecdotally, although most cases were probably of moderate rather than of severe aplastic anemia. Good supportive care (see following discussion) may contribute to this; in one series, 14 of 33 children recovered,[219] and children with moderate aplastic anemia have been found to have an excellent prognosis even without specific treatment.[220] A study of immunosuppressive therapy in which 21 patients were randomized (some to receive only supportive care) found no improvement in the control group after 3 months.[221] Spontaneous recovery is sufficiently rare in severe aplastic anemia that all modalities of current therapy should be initiated.

Supportive Care

Blood product support should be used judiciously to avoid sensitization, and blood product donors should never be from the patient's family for the same reason. Complete red cell phenotyping should be considered where feasible to minimize the potential risk of erythrocyte antibodies in patients who may receive long-term blood product support. All blood products should be irradiated because standard treatments are associated with profound immunosuppression. Leukoreduction appears prudent to reduce the potential risk of infection transmission and allosensitization because aplastic anemia patients may require a hematopoietic stem cell transplant. Exposure to potentially hazardous drugs or toxins should be eliminated. Treatment with single hematopoietic growth factors, such as granulocyte-colony stimulating factor (G-CSF) or erythropoietin should be avoided in part due to the resulting delay in definitive therapy.[222]

Bleeding

Platelet (and red cell) support has probably had the greatest impact on survival in aplastic anemia and has changed the cause of death from bleeding to infection. Platelets can be provided from several individual units of blood or, preferably, by platelet pheresis from a single donor to reduce antigenic exposure (see Chapter 36).

The main role of prophylactic platelet support is reduction of the risk of intracranial hemorrhage, which is a rare but potentially devastating event. The general threshold platelet count has traditionally been 20,000 cells/μL; however, this figure and the entire practice of prophylactic administration of platelet transfusions have recently been questioned.[223,224,225] Platelet transfusion at platelet counts below 10,000/μL in stable outpatients with chronic severe aplastic anemia was feasible and safe.[226] Chronic platelet transfusions for aplastic anemia are generally given when there are symptoms of bleeding or if the patient is at increased bleeding risk (e.g., toddlers learning to walk, patients with hypertension while on cyclosporine, patients with fever and infection). In some institutions a higher platelet transfusion trigger point of 20,000/μL is used during initiation of IST.

Other measures to reduce bleeding include maintenance of good dental hygiene, use of a soft toothbrush, stool softeners, and avoidance of trauma. Drugs that may interfere with platelet function, such as aspirin or nonsteroidal antiinflammatory drugs, should be avoided in thrombocytopenia. Antifibrinolytic agents such as aminocaproic acid and tranexamic acid may decrease bleeding, particularly from the gums and nasal mucosa.

Infections. There are few reported studies of infection in aplastic anemia.[227,228] Severe granulocytopenia may last for years, and infection remains the leading cause of death in aplastic anemia patients, particularly bacterial and fungal infections.[229,230] However, the immune systems of granulocytopenic patients remain intact; this is in contrast to the situation of patients with malignancies who receive chemotherapy and who experience simultaneous neutropenia and immunosuppression (as during IST for aplastic anemia). Neutropenia (and perhaps monocytopenia) increases the risk of bacterial infection in aplastic anemia.[211] Because neutropenia precludes the development of an inflammatory response, identification of an infected locus is often difficult. The bacterial organisms may be gram-negative bacilli such as *Escherichia coli, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa,* as well as gram-positive cocci, including *Staphylococcus aureus* and *S. epidermidis* and streptococci. Use of G-CSF has been studied in a few prospective analysis and other randomized trials, and these studies have been examined by meta-analysis. Gluckman and colleagues randomized aplastic patients receiving IST to prophylactic G-CSF treatment or not.[231] These investigators reported enhanced recovery of neutrophils in the G-CSF group but no effect on overall survival. More recently, Tichelli and colleagues randomized 192 aplastic patients to ATG/cyclosporine +/– G-CSF and reported significantly fewer infectious episodes and hospitalization days in the G-CSF group but no differences in overall survival or event-free survival between groups.[230] Interestingly they found that the lack of neutrophil response at day 30 post initiation of treatment was significantly associated with a lower response rate overall and a lower survival rate. They postulated that if confirmed by additional studies, the lack of neutrophil recovery at 30 days posttreatment could identify a group of patients in which alternative treatment might begin earlier than in the past. This study did not confirm a prior study by Teramura and colleagues that reported a lower incidence of relapse in patients treated with G-CSF.[232] Meta-analysis of a large number of studies has also reported that in aggregrate these studies showed no effect of G-CSF on overall survival, hematologic responses, or specific infections and no association of the use of G-CSF with MDS, AML or PNH.[233]

Immunosuppression due to preparation for BMT or as primary therapy for the aplastic anemia may lead to unusual bacterial, fungal, viral, and protozoan infections. Recommendations for specific antibiotics and other anti-infection agents are beyond the scope of this chapter, and regimens are changing rapidly as new generations of treatments are developed.

The use of routine prophylactic antibiotics has no demonstrated role in the “well” patient with aplastic anemia. In many institutions, guidelines are derived from experience in neutropenic cancer and post–BMT patients because prospective studies in pediatric aplastic anemia patients are rare.[229] In the opinion of many, even without supporting outcomes data, aplastic anemia patients with ANC less than 500 should receive antibacterial and antifungal prophylaxis. Patients undergoing IST are typically given prophylaxis for *Pneumocystis carinii*, although data supporting the need for this treatment are sparse or nonexistent. In the context of fever and neutropenia, complete evaluation and cultures of all possible sites should be followed by the administration of broad-spectrum parenteral antibiotics. Fungal infections occur frequently in neutropenic patients who have received repeated or extended courses of antibiotics; candidiasis and especially aspergillosis, which lead to sinusitis, lung disease, or disseminated infection, are distressingly frequent causes of death in aplastic anemia.[228] Antecedent or concurrent administration of steroids increases this risk. Aggressive introduction of antifungal treatment is indicated in the persistently febrile patient who is unresponsive to antibiotics or in the appropriate clinical setting.

Anemia. Red cells should be provided as clinically indicated. The hemoglobin should be maintained at a level consistent with normal activities if routine transfusions are to be used. Chronic anemia can be well tolerated once adaptation has occurred, and some children who can sustain a hemoglobin level greater than 6 to 7 g/dL without transfusions (i.e., a child who is not bleeding) may be carefully observed. Long-term transfusions lead to iron overload, with accumulation in critical organs. Permanent damage to heart, liver, and endocrine glands from iron overload may be prevented by iron chelation therapy.[234]

Treatment

Hematopoietic Stem Cell Transplantation. Hematopoietic stem-cell transplant offers curative therapy for aplastic anemia. The general topic of BMT is described in Chapter 8. The role of BMT in aplastic anemia treatment is discussed in Chapter 8.

Immunosuppression

Antithymocyte Globulin. *Antilymphocyte globulin* (ALG) and ATG (the sera produced by immunization of horses or rabbits with human thoracic duct lymphocytes or thymocytes) are highly cytotoxic reagents with activity against all blood and marrow cells, including progenitors. These reagents were initially used to decrease the rate of rejection of HLA-matched bone marrow. ALG and/or cyclophosphamide were also employed to permit at least temporary engraftment with mismatched marrow in aplastic patients without a matched donor.[157,158,159,235,236] Autologous recoveries occurred in some of these patients; they encouraged several groups to examine the use of ATG or ALG with and without haploidentical marrow. Treatment with ALG was superior to controls in both response rate and 3-year survival.[221] The addition of additional agents to ALG therapy can further enhance therapeutic effect.

ATG or ALG/ALS is often given to a total cumulative dose of 100 to 160 mg/kg, typically divided over 4 days. Immediate allergic reactions to ALG are rare and can be predicted by skin testing followed by desensitization in those who are allergic.[237] The patient begins to make antibodies to horse protein about 1 week after first exposure; at this point, equine antibodies are rapidly cleared from the circulation. This reduces the effective dose and enhances immune complex formation. *Serum sickness* due to immune complex deposition may manifest around 11 days after initiation of treatment as fever, a serpiginous rash at the volar–dorsal border of the hands and feet, arthralgia, myalgia, lassitude, and changes in urine sediment. Bronchospasm or liver chemistry abnormalities may also occur. A short course of corticosteroids is usually given (prednisone, 1 mg/kg) beginning at the start of ATG treatment and for 10 to 14 days to reduce ATG-related side effects. ATG binds to determinants on all cell types in blood and marrow and reduces platelet and granulocyte counts in addition to the lymphocyte counts, and it may lead to a positive Coombs test. Thrombocytopenia may require intensive blood product support during this time.[238]

Responses to ATG given as a single agent usually occur within the first 3-months, if at all, and blood count improvement by 3 months correlates with survival.[239] The earliest response to therapy may be heralded by the appearance of a few granulocytes and nucleated red cells in the circulation. Red-cell size distribution histograms typically show a macrocytic shoulder.[240] Reticulocytes appear, transfusions decline, and the hemoglobin level increases slowly. The white cell count rises next. The last cell line to return is often the platelets, whose numbers may remain low for months or even years. The recovering red cells are not normal; in addition to macrocytosis, Hb F level is increased, and fetal membrane antigens may remain present.[241] Long-term survivors (except those with successful transplants) often have residual abnormalities, such as thrombocytopenia, red cell macrocytosis, and elevated Hb F levels.[242] Clearly we do not understand either the mechanism of action of this poorly characterized drug, the ultimate course of patients with ATG-induced remissions, or the basis of their partial recovery.

Cyclosporine. Cyclosporine (formerly cyclosporin A) is a fungal cyclic undecapeptide and an effective immunosuppressive agent.[243] Among its many effects, cyclosporine can inhibit T cells, preventing production of IL-2 and IFN-γ.[160] About one half of patients who had failed ATG or ALG treatment subsequently experienced remission with cyclosporine.[244,245] Treatment with cyclosporine alone yielded significantly lower response rates and higher rates of disease progression as compared with combined therapy.[246,247]

Oral cyclosporine should be administered twice daily to maintain blood trough levels between 100 and 250 ng/mL as measured by radioimmunoassay, though the target levels may vary depending on laboratory methods used to determine cyclosporine levels. Hematologic responses can take weeks to months, and an initial trial period of 3 to 6 months is generally recommended.

Toxic effects from cyclosporine use are not insignificant and include hypertension, hypertensive encephalopathy, azotemia, hirsutism, gingival hypertrophy, coarsening of facial features, tremor, immunodeficiency, increase in serum creatinine levels, transient or irreversible nephrotoxicity, hepatotoxicity, seizures, and *P. carinii* pneumonia.[243] As with ATG, in vitro tests of the effect of cyclosporine on progenitor cells do not predict responses.[248]

Combination Immunosuppressive Therapy. The combination of ATG with cyclosporine has resulted in higher rates of hematologic recovery than either drug alone.[246,247,249] Importantly, intensive IST has greatly improved the results of therapy in two groups commonly refractory to ALG or ATG alone: children and patients with very severe disease.[250,251] In the National Institutes of Health (NIH) Clinical Center trial,[252] survival curves of those older and younger than 35 years of age were similar. A large study including both children and adults at the NIH reported a response rate of 67% at 43 months and a 5-year actuarial survival rate of 70% (86% for responders and 16% for nonresponders).[253] The Gruppo Italiano Trapianti di Midolio Osseo (GITMO)/European Group for Blood and Marrow Transplantation (EBMT) study of 100 patients with severe aplastic anemia including children (median age 16 years) treated with ALG, cyclosporine, prednisolone, and G-CSF found trilineage hematopoietic response in 77% after one or more courses of ALG.[254] Several trials in children have reported the efficacy of combined ATG and cyclosporine in the pediatric population with an overall response rate of close to 80%[255,256,250,251,257] (Table 6-2). Although greater lymphocyte depletion is achieved with rabbit ATG as compared to that with horse ATG, a randomized trial comparing horse ATG versus rabbit ATG in the upfront treatment of aplastic anemia demonstrated that superior hematologic response (68% versus 37%) and survival (96% versus 76%) was achieved with horse ATG.[258]

ATG is typically given over a 4-day course in combination with a 6 to 12 month course of cyclosporine. The lack of a unified definition for response complicates comparison of different studies, but generally a *complete response* (CR) refers to normal or functionally normal blood counts, a *partial response* (PR) denotes hemoglobin and platelet counts adequate to avoid the need for transfusion, and neutrophil counts typically greater than 500/μL, and *no response* commonly refers to continued severe aplastic anemia. Improvements in blood counts are delayed and may not be evident for many weeks. In a study including both children and adults, response rates, defined as at least a PR in two blood cell lineages, were 67% at 3 months and 71% at 6 months following initiation of combined ATG and cyclosporine therapy.[252] Cyclosporine should be tapered gradually with close monitoring of the blood counts prior to each decrease in dosage. A persistent drop in the blood counts can often be treated with either an increase in cyclosporine dosage or reinitiating the full dose. Some patients require continuous cyclosporine, and these patients should be maintained on the lowest effective dose. Relapse risk was reduced when cyclosporine was tapered slowly.[259] In a review of ongoing trials by the German multicenter group and the NIH, 29% and 14% of initial responders, respectively, were found to require continuous treatment.[253] The reoccurrence of frank pancytopenia generally requires a second course of ATG followed by full-dose cyclosporine. The relapse rate after combined IST varies widely from study to study. Most studies do not include only children. Kamio and colleagues recently reported a relapse rate of 16% in 264 responding aplastic patients[260] (which compared to 33% reported in an NIH study).[261] Relapse rates were even lower in a Japanese study.[232] Patients treated with IST often continue to have subnormal counts and may remain macrocytic. While the majority of patients respond within 6 months, delayed responses beyond that time may be seen for some patients.

Around 20% of patients in pediatric studies fail to respond to ATG and cyclosporine therapy (Table 6-2), while a recent study of mostly adult patients reported failure of response in around 40% of patients.[262] In

TABLE 6-2 Pediatric Studies of Immunosuppressive Therapy for Aplastic Anemia

Study	Years	Patient Number	Treatment	Follow-Up (years)	Response	Survival	Relapse	Clonal Abnormality

CR, Complete response; *CSA*, cyclosporine A; *DAN*, danazol; *MAA*, moderate aplastic anemia; *NR*, not reported; *OR*, overall response; *PR*, partial response; *SAA*, severe aplastic anemia; *vSAA*, very severe aplastic anemia.
*G-CSF added for SAA and vSAA.

most studies, failure of response is typically defined as persistence of severe aplastic anemia. In adult patients failing the first treatment with horse ATG, 63% of patients receiving a second course of horse ATG responded,[263] while 77% (23 out of 30) of patients initially treated with horse ATG and cyclosporine responded to a second course with rabbit ATG and cyclosporine.[264] In some small studies in children, the response rate to second immunosuppressoin has been less,[265] and treatment with rabbit ATG as a second therapy was associated with only 27% response rate.[266] In a large NIH study that included 77 children less than 18 years of age, of 14 relapsed patients, 6 were retreated with ATG and were alive at report, but the hematologic response of these patients was not reported.[261] Less acute reactions were noted when the source of ATG was varied between the first and second treatments. The time frame to response following a second course of immunosuppression was similar to that observed following initial treatment. Patients failing to respond to two courses of immunosuppressive therapy are unlikely to respond to a third treatment course.[267]

Because androgens are effective in treating some patients with aplastic anemia (see following discussion), the effect of combining androgen treatment with ATG was examined in several trials. Champlin and colleagues reported no difference in response rate or survival in patients with moderate to severe aplastic anemia.[268] Studies by Kaltwasser and colleagues[269] and the EBMT[270] found significantly higher response rates after ALG plus androgens (73% and 56%) than in patients receiving ALG alone (31% and 40%). A recent retrospective study in adults reported an overall response rate of 77% and overall survival rate of 78% at 5 years following treatment with ATG plus androgens.[271] At least one report showed increased relapse after ATG and cyclosporine when danazol was included in the treatment.[260] Because some patients with inherited causes of aplastic anemia may experience hematologic improvement following androgen therapy,[272] it is important to rule out an underlying inherited marrow failure syndrome. Androgen side effects may be unacceptable to some patients, and their use in acquired aplastic anemia in children is generally limited.

Relapse. Relapse after immunosuppressive therapy has been reported in around one third of patients in studies including both children and adults,[262,273] although lower rates of relapse may be attained with slow tapering of cyclosporine and continued maintenance doses at the lowest required cyclosporine dose for some patients. Lack of standardized definitions of *relapse* hamper comparison between studies. An EBMT study including both children and adults reported an actuarial relapse risk of 35% at 14 years.[274] Relapses were observed out to 10 years after treatment. Disease severity, age, sex, and etiology were not predictive of relapse. Large studies of relapse risk following IST therapy in the pediatric population are scarce. Results of these studies are summarized in Table 6-2.

Tichelli and colleagues studied the efficacy of repeated treatment with ALG for patients with severe aplastic anemia who either failed to respond to an initial course of ALG or who experienced hematologic relapse.[263] Transfusion independence was achieved in 63%, and survival probability was 52%± 8% at 10 years. No differences were noted between patients retreated for nonresponse versus relapse. No increases in acute toxicity were noted with additional courses of ALG, though the timing of serum sickness tended to occur earlier following repeat ALG administration. Relapse had little effect on survival for those patients responding to reinstitution of immunosuppression. A study of 22 patients refractory to combined ATG/cyclosporine reported an overall response rate of only 30% at 6 months. This study included two refractory patients under the age of 18, neither of whom responded to a second course of immunosuppression. Of 21 patients relapsing after ATG/cyclosporine treatment, an overall response rate of 65% was observed.[266] A retrospective study of 18 relapsed or refractory patients reported responses to a third course of an ATG-containing regimen only for those patients who had previously responded to a prior course of treatment.[267]

Complications of Immunosuppressive Therapy. Patients treated for aplastic anemia with immunosuppressive therapy have an increased risk of developing clonal hematopoietic disorders.[275,276] Because ATG and cyclosporine are not associated with an increased risk of MDS or leukemia in patients treated for other disorders, these complications are believed to result from the underlying dyspoiesis of aplastic anemia. In an analysis of 860 aplastic anemia patients treated with immunosuppression, 42 malignant conditions were reported, including 19 cases of PNH, 11 cases of myelodysplasia, 15 cases of acute leukemia, 7 cases of solid tumors, and 1 case of non-Hodgkin's lymphoma.[277] Of 748 aplastic anemia patients treated with transplantation, 9 malignancies were reported: 2 acute leukemias and 7 solid tumors. The cumulative incidence of developing a malignant tumor at 10 years was 18.8% following immunosuppression and 3.1% following transplantation. A recent NIH study of 122 patients treated with immunosuppression showed a 33% actuarial risk of developing a clonal hematopoietic disorder at 10 years.[4] An increased risk of clonal abnormalities as high as 21.9%[278] has been reported in some studies of pediatric patients with aplastic anemia. An increased risk of MDS or AML has also been observed in pediatric patients (Table 6-2). Certain clonal abnormalities, such as monosomy 7, were associated with worse clinical outcomes.[279] While an association between G-CSF use and risk of clonal disease has been observed,[278] in the absence of randomized studies, the question of causality remains unanswered. These data suggest that a clonal transformation of stem cells may underlie aplastic anemia, at least in a subset of patients. Prolonged survival caused by ATG/ALG/CYA may permit the expected clonal evolution.

Transplantation versus Immunosuppression. The decision to treat with immunosuppression versus an HLA-identical sibling stem-cell transplant for the 25% of patients for whom a suitable donor is available is based on a consideration of risks and benefits that vary depending on patient age and neutrophil count. Upfront toxicities associated with the conditioning regimens, GVHD and graft rejection are the major problems associated with stem-cell transplantation, but this treatment offers the potential for long-term cure. Cytotoxic and immunosuppressive therapy is associated with lower acute toxicities but often yields incomplete hematologic recovery and is associated with late mortality from long-term complications such as relapse and clonal hematologic disorders. Comparison of outcomes with BMT and immunosuppression in children support the benefit of HLA-matched sibling stem-cell transplant. Kojima and colleagues[280] reported a study of 100 children under the age of 17 years with aplastic anemia between 1984 and 1998. Thirty-seven patients received allogeneic BMT and 63 patients received immunosuppression with either ATG plus danazol or ATG and cyclosporine with or without danazol. Some patients also received G-CSF. Eleven patients initially treated with IST received subsequent salvage treatment with unrelated donor transplant. The projected 10-year survival was 55% ± 8% with immunosuppression and 97% ± 3% with transplant. Failure-free survival at 10 years was 40% ± 8% for the immunosuppression group and 97% ± 3% for the transplant group. Seven patients in the immunosuppression group developed MDS with monosomy 7, and the estimated 10-year cumulative incidence of MDS was 20% ± 7%.

A recent report from the EBMT analyzed 1765 patients with aplastic anemia receiving initial treatment with either an HLA-identical sibling transplant or immunosuppressive therapy.[281] Analysis was performed on an "intent-to-treat" basis. Patients were aged 1 to 50 years and treated between 1974 and 1996. Five hundred eighty-three patients received HLA-identical sibling transplant, and 1182 patients received immunosuppression. A comparison of immunosuppression versus BMT in patients stratified by age and neutrophil count showed superior failure-free survival with transplant for children regardless of their neutrophil count. The advantage of transplant increased with increasing follow-up time, most likely due to the ongoing risks of late relapse and evolution to myelodysplasia and leukemia in the group receiving immunosuppression. Children have a lower mortality with stem-cell transplant and a longer posttreatment life expectancy, placing them at higher risk for late complications than older adults. Thus the current recommendation is to treat young patients (10 years or younger) with HLA-identical sibling stem-cell transplant when a suitable donor is available. Patients with severe disease also do better with BMT. It is important to note that many patients on these studies of long-term outcomes were treated prior to the development of current combined immunosuppressive regimens containing both ATG and cyclosporine.

For those patients lacking a suitable HLA-matched sibling donor, ATG and cyclosporine treatment is generally the preferred line of therapy given the higher risk of toxicities and morbidity associated with current alternative donor transplant regimens. For patients who fail to respond to an initial course of ATG and cyclosporine, either a second course of ATG/cyclosporine or an alternative donor hematopoietic stem-cell transplant may be considered. The risks and benefits of each approach will vary for each patient, but the risks associated with prolonged delay to potential transplant[282] should be weighed against the most current data on alternative donor regimens.

Hematopoietic Growth Factors. Although patients with aplastic anemia do not have a deficiency of most hematopoietic growth factors (see previous discussion), it was hypothesized that pharmacologic levels might stimulate hematopoiesis of one or more cell lines.[208] Small trials of GM-CSF, G-CSF, IL-3, IL-1, IL-6, and SCF in mostly adult patients with aplastic anemia do not support the use of growth factors as primary treatment for aplastic anemia, and serious side effects were noted with some agents. To date, no consistent benefit in terms of response rate or survival following the adjunctive use of growth factors such as G-CSF in immunosuppressive regimens has been observed (see previous discussion).[250,283] No improvement in overall response rates were noted in a retrospective study of 18 pediatric patients receiving GM-CSF in addition to ATG and cyclosporine.[284] Responses to single or combined growth factors have been reported in a few refractory patients.

G-CSF is associated with flulike symptoms, bone pain, and splenomegaly. Symptoms of “cytokine flu”—fever, rash, hives, headache, and myalgia—are common but do respond to acetaminophen or resolve with the passage of time. Bone pain may be a symptom of increased marrow activity, though this is more commonly seen with G-CSF. At higher doses, the severity of symptoms increases, and there may be evidence of visceral engorgement and fluid retention.

The potential risk of promoting or stimulating the development of abnormal hematopoietic clones leading to a further increased risk of myelodysplasia or leukemia following prolonged treatment with growth factors remains a concern in aplastic anemia patients. Although associations between G-CSF treatment and the subsequent development of MDS and leukemia have been reported,[285] in the absence of randomized prospective trials, it is not clear whether this represents an effect of growth factor treatment or merely an association reflecting the natural history of aplastic anemia of sufficient severity to warrant the addition of G-CSF.

Eltrombopag. A recent report suggests that the thrombopoietin-mimetic eltrombopag may have activity in aplastic anemia.[286] Thrombopoietin is a major regulator of platelet production and is the ligand for c-mpl on megakaryocytes. C-mpl is also expressed on hematopoietic stem cells, and mice deficient in either thrombopoietin or c-mpl show deficiencies in hematopoietic stem and progenitor cells.[287,288] In addition a significant number of children with amegakaryocytic thrombocytopenia develop pancytopenia (discussed in Chapters 30 and 34). In a phase 2 study, investigators at the NIH demonstrated a 44% hematologic response rate of aplastic anemia patients refractory to IST. In this nonrandomized study, 9 out of 25 patients became platelet transfusion–independent, 6 out of 25 demonstrated increased hemoglobin levels, and 9 out of 25 showed increased leukocyte counts within 3 months of treatment with minimal side effects. Studies in children have not been reported, and this study has not been reproduced to date, so caution is warranted in utilizing this drug long-term outside of a clinical trial.

Androgens. Androgens no longer have a primary role in the management of aplastic anemia, unless the first-line therapies discussed above are unavailable or unsuccessful. As described earlier, androgens have been used as adjuncts to immunosuppression

The mechanism of action has been reviewed extensively by Gardner and Besa.[289] Androgens increase erythropoietin production,[290] and stimulate erythroid stem cells.[291] Hemoglobin levels increase in normal males at puberty and in patients treated with androgens for arthritis, breast cancer, or in old age. Shahidi and Diamond were the first to report success with testosterone[292] and large confirmatory series were published from France[293] and Mexico.[294] However, later critical evaluations revealed no evidence supporting the use of androgens. Despite the use of androgens, greater than 75% mortality has been reported in children[216] and adults.[295] Androgen-treated patients often did not do as well as those who were not treated with these hormones.[217,296] The older publications often failed to distinguish moderate from severe patients. Camitta and colleagues performed a prospective, multicenter analysis beginning in 1974 and concluded that androgens (whether oral or intramuscular) were no more effective than supportive care alone for severe aplastic anemia.[297,298]

Improvement, if it occurs, is usually greatest in the hematocrit, though increases in the granulocyte and platelet counts may also be seen. Response may take weeks to months, and trials of at least 3 months are recommended before declaring a patient as unresponsive. The major side effect of androgens is liver toxicity. Cholestatic jaundice and hepatomegaly are usually reversible. Peliosis hepatis (blood lakes) have been reported.[299] Hepatic tumors are a serious risk, although the pathologic picture is usually that of a benign adenoma; such tumors may be reversible when use of the androgen is discontinued. Other side effects include masculinization with hirsutism, baldness, deepening of the voice, and enlargement of the genitalia. Acne, flushing of the skin, nausea, and sodium and fluid retention also occur. The appetite is stimulated, and there is weight gain with increased muscular development. There may be an increase in the rate of skeletal maturation, with eventual premature fusion and ultimate short stature.[300] All patients who receive androgens should be monitored with frequent liver function testing, annual liver ultrasound examinations, and annual bone age determinations.

Corticosteroids. Modest doses of methylprednisolone are generally given during ATG or ALG treatment to lessen the side effects of serum sickness. As a single agent, very high doses of corticosteroids have been reported to lead to responses in a few patients.[301,302] Treatment with high-dose steroids is associated with substantial toxicities, including hypertension, hyperglycemia, fluid retention, potassium wasting, psychosis, aseptic necroses of femoral and humeral heads, and increased susceptibility to fungal infections. Given the higher response rate and lower toxicity profile of ATG, high-dose steroids are not recommended as first-line therapy for aplastic anemia.

Splenectomy. Splenectomies were performed until recently, perhaps for want of something better to offer to patients. A review in 1957 indicated improvements in 20 of 35 patients.[303] More recently, the operation has been performed to facilitate supportive care.[304] Unless there are clear indications of hypersplenism significantly impeding platelet and red cell transfusion support, the operation does not seem warranted.

Other Therapies. New therapeutic regimens are aimed at improving rates of hematologic response and minimizing acute and long-term complications of therapy.[162] The current status of a few investigational regimens is summarized below.

Cyclophosphamide. Administration of high doses of cyclophosphamide is an effective IST and is not myeloablative in normal hosts. Historically a few patients who received high-dose cyclophosphamide as preparation for marrow transplant rejected their grafts and had autologous recovery. An early study of treatment with this drug without transplant indicated a CR in 7 of 10 patients treated with 45 mg/kg per day for 4 days.[305] A study of 19 previously untreated patients with aplastic anemia reported a 73% overall response rate at 24 months with a 65% probability of achieving CR at 50 months and an 85% survival rate at 24 months.[306] No relapses or clonal disorders were observed in the responding patients. A phase III prospective randomized trial compared high-dose cyclophosphamide plus cyclosporine to ATG plus cyclosporine as first-line therapy.[307] The trial was terminated prematurely due to invasive fungal infections and three early deaths in the group treated with cyclophosphamide plus cyclosporine (none were noted in the ATG/cyclosporine group). Responses at 6 months' follow-up were seen in 6 of 13 (46%) patients treated with cyclophosphamide plus cyclosporine versus 9 of 12 (75%) patients treated with ATG plus cyclosporine. Trials of high-dose cyclophosphamide as a single agent in patients refractory to prior treatment with IST reported a 53% response rate and 59% survival rate at a median follow-up of 29 months.[308] The generally prolonged time to response and associated toxicities are potentially limiting factors, and additional studies are required to determine whether long-term complications such as relapse or clonal disease will be superior to that associated with ATG and cyclosporine.

Alemtuzumab. Several recent adult studies have examined the use of alemtuzumab, a humanized anti-CD52 monoclonal antibody, in both naïve and relapsed/refractory aplastic anemia. Alemtuzumab eliminates CD52+ lymphocytes by both direct cytotoxicity and by complement-mediated cellular lysis. The studies are small and included naïve as well as relapsed and refractory patients.[309,310-312] Dosage ranged from 70 to 100 mg (total) delivered over 5 to 10 days either intravenously or subcutaneously with or without low dose Cytoxan as a chronic maintenance. Study results were variable, with 30% to 50% response rates (combined CR and PR) and approximately 70% to 80% overall survival. Side effects also varied with multiple infectious complications, clonal evolution (MDS with monosomy 7) and PNH and in one case progressive multifocal leukoencephalopathy. Studies are ongoing, including a consensus regimen by the Severe Aplastic Anemia Working Group in Europe.[312]

Recombinant Humanized Anti-IL-2 Receptor Antibody. The IL-2 receptor is found on activated T cells and is required for T-cell expansion.[313] A pilot study of 17 patients with moderate aplastic anemia treated for 3 months with a humanized monoclonal antibody against the IL-2 receptor (daclizumab) reported improved blood counts in 38% of patients.[314] Daclizumab was well tolerated with minimal side effects. Further studies on the use of daclizumab in aplastic anemia are warranted.

Mycophenolate Mofetil. Mycophenolate mofetil (MMF; Cell-Cept) is the prodrug of mycophenolic acid, which inhibits B- and T-cell proliferation through inhibition of inosine monophosphate dehydrogenase, which is involved in guanine nucleotide synthesis.[315] MMF has been in clinical use for prevention of solid organ transplant rejection and to treat autoimmune diseases. Although generally well tolerated, MMF side effects include leukopenia and marrow suppression. A study of 104 patients with severe aplastic anemia treated with ATG, cyclosporine, and MMF reported an overall response rate of 62% at 6 months.[316] Relapses were seen in 37% of responders with over half of relapses occurring while the patients were still receiving MMF. Clonal abnormalities were noted in 8.7% of patients after a median follow-up of 42 months. No difference in overall survival was noted between children and adults. The addition of MMF did not result in improved rates of response, relapse, or clonal abnormalities in comparison to those reported following treatment with ATG and cyclosporine.

ACQUIRED PURE RED CELL APLASIA

Acquired pure red cell aplasia (APRCA) is a term that embraces a range of incompletely understood aregenerative anemias (sometimes associated with neutropenia and thrombocytopenia).[317] Unifying characteristics of this broad range of disorders are anemia and a paucity of recognizable erythroid precursors in the bone marrow. The anemia may be macrocytic if some residual "stress" erythropoiesis is extant. If there is complete arrest of erythropoiesis, the anemia will be normocytic or even slightly microcytic and hyperchromic if the arrest of erythropoiesis has existed for 2 months or more because red cell volume shrinks as red cells age in the circulation. In some cases, particularly those associated

Box 6-4 Classification of Acquired Pure Red Cell Aplasia

PRIMARY

Autoimmune (antibodies against erythropoietin, erythroid progenitors, and precursors and T-cell suppression of erythropoiesis)
Idiopathic (transient erythroblastopenia of childhood)
Preleukemic (the 5Q-syndrome)

SECONDARY

Thymoma
Nonthymic solid tumors (gastric, breast, lung carcinomas, Kaposi sarcoma)
Hematologic malignancies (lymphoma, CLL, CML)
Infections (particularly parvovirus)
Chronic hemolytic anemia (aplastic crisis)
Collagen vascular disease
Drugs and chemicals (chemotherapy particularly azathioprine in renal transplant)
Pregnancy
Severe renal failure
Severe vitamin and calorie malnutrition

with parvovirus infection, mild neutropenia, and even thrombocytopenia may coexist with the anemia. Thus the term *pure red cell aplasia* may be honored in the breech.

Much of our understanding of APRCA seen in adults has been derived from the clinical research of Sanford Krantz and Emmanuel Dessypris and their colleagues at Vanderbilt University.[318] The reader is referred to Dr. Dessypris's excellent monograph for a history and reasonable classification and description of these arcane disorders. A more recent set of reviews has been edited by Stephen A Feig and Melvin H Freedman.[319]

APRCA may be classified as outlined in Box 6-4.

Primary Acquired Pure Red Cell Aplasia

Circulating antibodies and suppressing T cells: Dessyrpis and Krantz have carefully described the course of patients who suddenly develop antibodies reactive with erythroid precursors that presumably suppress either erythroid progenitors (BFU-E and CFU-E) or recognizable precursors or both. Dessyypris's monograph[318] and Krantz's more recent review in the volume edited by Feig and Freedman[319] exhaustively document the evidence for such antibodies and their suppressing activities. In brief the antibodies may arise de novo and hence are considered primary or in the setting of immune deficiency, neoplastic disease, collagen vascular disease, or infection in which they are considered secondary. In either case, the antibodies cause severe aregenerative anemia and, though they are often responsive to immunosuppressive therapy, commonly return to the circulation and cause relapse unless therapy is continued for protracted periods of time. Fortunately antibody mediated APRCA is quite rare in children. The pathophysiology, course, and treatment of the disease are better understood in adults.

Autoantibodies that bind and inhibit erythropoietin and are responsible for erythroid aplasia were first inferred from the work of Jepson and Lowenstein.[320] Though similar reports later emerged, three of which were associated with recombinant erythropoietin therapy, the pathophysiologic evidence for such antibodies was marginal until 2002, when French investigators reported a high incidence of antierythropoietin antibodies in patients (largely with renal failure) who had been treated with a particular brand of recombinant erythropoietin that had been altered by a variation in glycosylation and by improper storage and thereby rendered antigenic.[321] The findings have been confirmed worldwide. The offending brand of erythropoietin has since been modified, and the incidence of such autoantibodies has been markedly reduced. IST induces a disappearance of these antibodies in most cases. Successful treatment with a peptide-based erythropoietin-receptor agonist has been reported.[322] In truth it might be reasonable to classify the PRCA that results from antierythropoietin antibodies that arise in the face of recombinant erythropoietin treatment as an example of secondary PRCA.

A case of primary APRCA associated with T-cell suppression of erythropoiesis by large granular lymphocytes that carried both T-cell and monocyte surface markers was described in 1983 by Lipton and his associates.[323] In this case the T cells recognized erythroid but not myeloid progenitors in the context of HLA and suppressed in vitro erythropoiesis in the patient and in HLA-identical normal individuals. Prior to and since that report there have been several papers that describe such T cells in cases of APRCA,[317] but the Lipton study provides the best evidence for an HLA-specific erythroid inhibition by an offending clone of T cells. Interestingly this patient was rapidly cured by treatment with cyclophosphamide.

Transient Erythroblastopenia of Childhood

Though probably described in the 1960s by Schmid and by DiGiacomo and their colleagues,[324,325] who each reported a potpourri of cases of APRCA, transient erythroblastopenia of childhood (TEC) was first clearly enunciated by Wranne in 1970.[326] This frequent disease is well described by Glader.[319] TEC is certainly the most common aregenerative anemia in childhood and is likely to be a very frequent complication of a host of relatively trivial viral infections. It is well established that erythropoiesis is briefly interrupted during such infections in most individuals. But anemia is not documented because the red cell life span is 120 days, and the suppression usually lasts for only a week. In many patients the suppression is protracted, and anemia ensues. Spontaneous recovery without any treatment is virtually the rule, but confusion may result if the pediatrician sees the patient at the time of recovery when reticulocytosis is in full spate.[327] This may lead to a false diagnosis of hemolytic anemia and an ensuing workup that simply produces more anemia in the blood as well as in the pocketbook. It is important to suspect TEC in an otherwise healthy child whose blood smear does not suggest a red cell disorder or leukemia. A bone marrow examination is not indicated in the vast majority of cases.[328] Because neutropenia and mild thrombocytopenia are common concomitants of many viral infections, TEC is often not a "pure" red cell disease; however, the anemia is usually the more striking anomaly.

Many efforts have been made to implicate parvovirus serotype 19 as an offender in TEC. Though rare cases have been noted, parvovirus is usually not detected.[329-331]

It is, however, a serious risk in patients with immune deficiency, such as those undergoing organ or marrow transplantation, and in patients with foreshortened red cell lifespans, such as sickle cell anemia or hemolytic anemias (see Chapter 20).

Preleukemia (the 5Q-syndrome)

The 5Q-syndrome is an acquired clonal defect in which a segment of chromosome 5Q bearing at least 40 genes is deleted. Severe aregenerative anemia, absent marrow erythroblasts, abnormal megakaryocytes, and a high incidence of acute myelogenous leukemia are the results. The recent discovery by Ebert and his colleagues that the responsible deletion is the gene encoding a ribosomal protein[332] classifies the 5Q- syndrome as an acquired and clonal form of the Diamond–Blackfan anemia.[333] It is discussed in extenso in Chapters 7 and 51.

Secondary Acquired Pure Red Cell Aplasia

The secondary causes of APRCA are very rare in childhood, and thymoma is even rarer. Freedman and Feig reviewed the pediatric literature in 1993,[319] and little has emerged since. Thymoma, when associated with PRCA may be successfully treated with surgery coupled with immunosuppression or intravenous immunoglobulin.[334-337]

Very rarely, children with B-cell proliferative diseases may have concomitant PRCA, but almost all of the therapeutic experience is recorded in adults. Of the few cases of PRCA reported in children, most are in the setting of immunodeficiency.

Drug-induced PRCA is by far the most common cause of secondary PRCA in childhood, and azathioprine treatment of renal transplant rejection is by far the commonest offender.[338] The latter drug usually causes a megaloblastic anemia, but it may result in near total aplasia. Severe renal failure may also cause PRCA in childhood.

CHAPTER 7

Inherited Bone Marrow Failure Syndromes

Monica Bessler, Philip J. Mason, Daniel C. Link, and **David B. Wilson**

CHAPTER OUTLINE

INHERITED BONE MARROW FAILURE SYNDROMES ASSOCIATED WITH PANCYTOPENIA	INHERITED BONE MARROW FAILURE SYNDROMES ASSOCIATED WITH ISOLATED CYTOPENIAS
Fanconi Anemia	Diamond-Blackfan Anemia
Dyskeratosis Congenita	Congenital Dyserythropoietic Anemias
Shwachman-Diamond Syndrome	Severe Congenital Neutropenia
Cartilage-Hair Hypoplasia	Inherited Thrombocytopenias
Pearson Syndrome	Amegakaryocytic Thrombocytopenia
Familial Marrow Dysfunction	Thrombocytopenia with Absent Radii

Inherited bone marrow failure syndromes (IBMFSs) are a diverse collection of genetic disorders associated with inadequate blood cell production. Bone marrow failure (BMF) may manifest as an isolated cytopenia (pure red cell aplasia, neutropenia, or thrombocytopenia) or as pancytopenia with the clinical picture of aplastic anemia. Table 7-1 summarizes the more common IBMFSs, the blood cell lineages affected, the genes mutated and their modes of inheritance, and the pathways involved. Other organ systems are often affected by these genetic abnormalities, resulting in birth defects or clinical disease in nonhematopoietic organs. Birth defects and extra hematopoietic manifestations are often characteristic and may be noticed before the onset of BMF or may be the only manifestations of disease. BMF may be present at birth (congenital BMF) or develop later in life. IBMFSs are not always inherited; the genetic mutations responsible may occur de novo during early embryonic development. Several, but not all, IBMFSs are characterized by a predisposition for malignant transformation, in particular of the hematopoietic system, including the development of myelodysplastic syndrome (MDS) and acute leukemia, but also for a variety of other forms of cancer (see Table 7-1).

The prevalence of IBMFSs is difficult to ascertain because BMF registries are biased by referral, founder effect, and the enrollment of mainly pediatric patients. The incidence of IBMFSs has been estimated to be 40 to 65 per 10^6 live births.[1,2] Originally, IBMFSs were considered to be mainly diseases of childhood. In children 25% to 30% of BMF cases were thought to have a genetic cause, whereas among adults an inherited genetic cause was considered in only a minority of patients. However, more recent data suggest that the prevalence of IBMFS patients has probably been underestimated, particularly in adults. In addition, improved medical care after bone marrow transplantation (BMT) has extended life expectancy and shifted the management of IBMFS patients to adult hematologists.

Timely and correct diagnosis of an IBMFS is paramount because management of an IBMFS differs from that of acquired BMF. Treatment of IBMFSs often requires a complex interdisciplinary approach that includes hematologists, geneticists, hematopathologists, BMT specialists, oncologists, endocrinologists, orthopedists, neurologists, gastroenterologists, nephrologists, dentists, and other specialists. Differentiation between acquired and inherited BMF is of importance not only for affected individuals but also for their family members. Early and correct diagnosis of an IBMFS allows intensified and focused disease surveillance, anticipatory guidance, and avoidance of treatment-related toxicities. Identification of a gene mutation known to be associated with BMF can definitively establish the diagnosis before clinical symptoms advance and help identify an unaffected bone marrow donor in the family. It is therefore imperative that at the time of initial evaluation maximal effort be made to distinguish acquired from inherited forms of BMF.

Considerable advances have been made in the last 15 years in elucidating the genetic causes of IBMFSs

AML, Acute myeloid leukemia; *AR*, autosomal recessive; *AD*, autosomal dominant; *ATR*, ataxia-telangiectasia and Rad3 related; *GCSF*, granulocyte colony-stimulating factor; *MDS*, myelodysplastic syndrome; *MIM #*, Mendelian Inheritance in Man with responsible gene identified; *MIM %*, Mendelian Inheritance in Man with responsible gene not identified; *XLR*, X-linked recessive.

*No specfic ribosomal gene mutation has been assocated with AML/MDS.

†Specific mutations only.

(see Table 7-1). In the past investigations of IBMFSs were largely restricted to careful observations and descriptions of clinical manifestations in the patient and family, as well as meticulous study of the clinical course of the disease. However, innovations in genomic sequencing technology have led to the identification of a rapidly increasing number of genes that when mutated are responsible for certain IBMFSs. Characterization of these genes and investigation of their role in hematopoiesis are powerful new tools to explore the pathways responsible for BMF.

Traditionally, IBMFSs have been classified according to their clinical features. Increasingly this classification scheme is being supplanted by one based on the affected biochemical pathway (see Table 7-1). Surprisingly, the affected pathways often entail "housekeeping" functions important for most cell types (DNA repair, telomere maintenance, or ribosome biosynthesis) rather than functions unique to hematopoietic cells. Why hematopoiesis is preferentially and sometimes even exclusively affected by a derangement in these pathways is intriguing and the focus of current investigations in the field of BMF research. One feature these pathways share is that their derangement usually causes the activation of p53, suggesting that this molecule plays a central role in the pathogenesis of IBMFSs (Fig. 7-1).[3,4]

With the increased knowledge of how the genetic framework influences the development of BMF, distinguishing between inherited and acquired BMF has become more difficult. Previously, IBMFSs were restricted mainly to patients with BMF caused by gene mutations with high disease penetrance. Today, it is increasingly being recognized that, in addition, a growing number of patients have BMF caused by gene mutations that have low or very low penetrance, with disease developing only occasionally or just under certain precipitating circumstances. Thus the majority of patients in whom acquired idiopathic aplastic anemia was previously diagnosed may have an underlying genetic component. Figure 7-1 schematically illustrates the possible interrelationship between genetic mutation, environment, and gene modifiers in the pathogenesis of BMF. In the coming years, advances in DNA sequence technology are likely to bring a wealth of new information to the field of BMF research that in combination with the power of bioinformatics is likely to shift some of the current disease paradigms. The increased understanding of the genetic components and their role and importance in the pathogenesis of disease will allow us to improve the diagnosis, management, and treatment of patients with BMF.

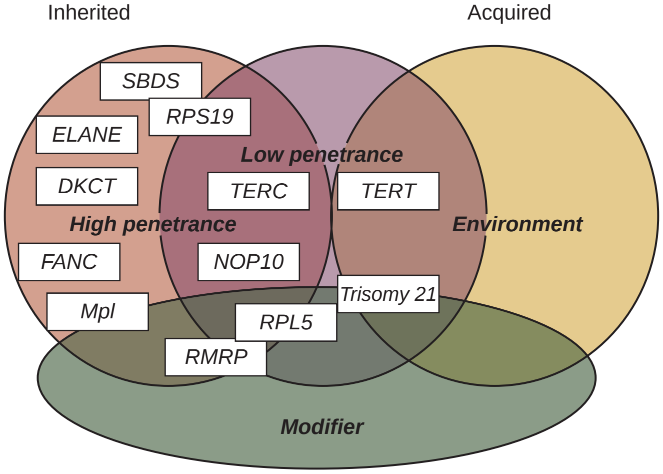

Figure 7-1 Interrelationships of disease penetrance of a genetic mutation, the environment, and modifiers in the pathogenesis of bone marrow failure.

Box 7-1 Fanconi Anemia

Fanconi anemia (FA, MIM #227650) is an autosomal recessive and X-linked disorder characterized by progressive bone marrow failure, congenital abnormalities, and a predisposition for malignant disease. Cells from patients with FA exhibit spontaneous chromosomal instability and a characteristic hypersensitivity to DNA interstrand cross-linking agents such as diepoxybutane (DEB) and mitomycin C (MMC).

INHERITED BONE MARROW FAILURE SYNDROMES ASSOCIATED WITH PANCYTOPENIA

Fanconi Anemia

Fanconi anemia (FA) is a genetically and phenotypically heterogeneous disorder. The disease is named after the Swiss pediatrician Guido Fanconi (1892-1979), who first described the syndrome in 1927.[5] Clinically, FA is characterized by a variety of congenital abnormalities, progressive BMF, and a propensity for the development of leukemia and other forms of cancer. Cells from FA patients have a striking hypersensitivity to DNA interstrand cross-links[6]; this trait has become the basis of a clinical diagnostic test for FA (Box 7-1).[7]

Epidemiology

The incidence of FA is difficult to ascertain. The Fanconi Anemia Research Fund, Inc., estimates that about 30 persons with FA are born in the United States each year; this would indicate that the prevalence of FA is about 2.5 per million and the carrier frequency is approximately 1 in 180.[8] The male-to-female ratio is 1.2 : 1.[9] FA has been reported in all races and ethnic groups. The world's highest prevalence of FA, caused by a founder effect, is seen in Spanish gypsies, who have a carrier frequency of 1 in 70.[10] A high prevalence of FA is also found in individuals of Ashkenazi Jewish decent, who have an approximate heterozygous frequency of 1 in 77,[11] and in South African Afrikaans, in whom carrier frequency is estimated to be 1 in 83.[12]

Clinical Manifestations

The clinical manifestations of FA are heterogeneous (variable penetrance and expressivity; for definitions, see Box 7-2). Affected family members can have a wide variety of abnormalities (variable expressivity).[13-15] Even monozygotic twins have been described to differ in their physical and hematologic manifestations.[15] However, the occurrence of malformations is nonrandom. Siblings are usually

Box 7-2 **Heritability, Penetrance, and Expressivity**

Heritability, penetrance, and expressivity are distinct but related concepts. *Heritability* is the number of family members who have inherited a genotype versus the number of family members who have not. *Penetrance* is defined by the number of individuals who show a phenotype versus the number of individuals who carry the genotype. *Expressivity* measures the variability and severity of an expressed phenotype.

concordant for the presence or absence of multiple congenital abnormalities; likewise, the age at onset of hematologic manifestations is similar within an individual family.[16] Thus the variability in clinical findings appears to be to some extent linked to the different genotypes. The emergence of revertant cells leading to hematopoietic mosaicism further contributes to disease variability (see the section on Somatic Mosaicism, Functional Reversion, and Attenuation of Fanconi Anemia Cells).[15,17-19,20-22] Originally, the diagnosis of FA was based on the presence of both aplastic anemia and a specific, though broad, range of physical abnormalities.[23] With the availability of more sensitive and specific tests for the diagnosis of FA, including the availability of genetic testing, it has become evident that a significant proportion of patients lack congenital abnormalities (25% to 40%) or fail to develop aplastic anemia.[24-28] Nevertheless, these individuals are still at risk for late complications such as leukemia and cancer.

Congenital Abnormalities

The frequency and nature of congenital abnormalities within the FA population is summarized in Box 7-3. Figure 7-2, *A* shows a 1-year-old girl with FA, and Figure 7-2, *C* shows a 12-year-old boy with several classic phenotypic features, including short stature, microencephaly, broad nasal bridge, epicanthal folds, micrognathia, café-au-lait spots and hypopigmentation, and one absent thumb and one triphalangeal thumb. FA patients may have a combination of the congenital anomalies listed or none of them.

Box 7-3 **Specific Types of Anomalies in Fanconi Anemia**[*26-28]

SKIN (40%)

Generalized hyperpigmentation on the trunk, neck, and intertriginous areas; café-au-lait spots; hypopigmented areas

BODY (40%)

Short stature, delicate features, small size, underweight

UPPER LIMBS (35%)

Thumbs (35%): absent or hypoplastic; supernumerary, bifid, or duplicated; rudimentary; short, low-set, attached by a thread; triphalangeal, tubular, stiff, hyperextensible
Radii (7%): absent or hypoplastic (only with abnormal thumbs); absent or weak pulse
Hands (5%): clinodactyly; hypoplastic thenar eminence; six fingers; absent first metacarpal; enlarged, abnormal fingers; short fingers; transverse crease
Ulnae (1%): dysplastic or absent

LOWER LIMBS (5%)

Feet: toe syndactyly, abnormal toes, flatfeet, short toes, clubfeet, six toes, supernumerary toe
Legs: congenital hip dislocation, Perthes disease, coxa vara, abnormal femur, thigh osteoma, abnormal legs

GONADS

Males (25%): hypogenitalia, undescended testes, hypospadias, abnormal genitalia, absent testis, atrophic testes, azoospermia, phimosis, abnormal urethra, micropenis, delayed development
Females (2%): hypogenitalia; bicornuate uterus; abnormal genitalia; aplasia of uterus and vagina; atresia of uterus, vagina, and ovary

OTHER SKELETAL ANOMALIES

Head (20%) and face (2%): microcephaly, hydrocephalus, micrognathia, peculiar face, bird-like face, flat head, frontal bossing, scaphocephaly, sloped forehead, choanal atresia, dental abnormalities
Neck (1%): Sprengel deformity; short, low hairline; webbed
Spine (2%): spina bifida (thoracic, lumbar, cervical, occult sacral), scoliosis, abnormal ribs, sacral agenesis, sacrococcygeal sinus, Klippel-Feil syndrome, vertebral anomalies, extra vertebrae

EYES (20%)

Small eyes, strabismus, epicanthal folds, short or almond-shaped palpebral fissures, hypertelorism, ptosis, slanting, cataracts, astigmatism, blindness, epiphora, nystagmus, proptosis, small iris

EARS (10%)

Deafness (usually conductive); abnormal shape; atresia; dysplasia; low-set, large, or small; infections; abnormal middle ear; absent eardrum; dimples; rotated; canal stenosis

KIDNEY (20%)

Ectopic or pelvic; abnormal, horseshoe, hypoplastic, or dysplastic; absent; hydronephrosis or hydroureter; infections; duplicated; rotated; reflux; hyperplasia; no function; abnormal artery

GASTROINTESTINAL SYSTEM (5%)

High-arched palate, atresia (esophagus, duodenum, jejunum), imperforate anus, tracheoesophageal fistula, Meckel diverticulum, umbilical hernia, hypoplastic uvula, abnormal biliary ducts, megacolon, abdominal diastasis, Budd-Chiari syndrome

UROGENITAL

Males (25%): Micropenis, penile-scrotal fusion, undescended or atrophic or absent testes, hypospadias, chordee, phimosis, azoospermia
Females (2%): bicornate uterus, aplasia or hypoplasia of vagina and uterus, atresia of vagina, hypoplastic uterus, hypoplastic or absent ovary, hypoplastic fused labia

CARDIOPULMONARY SYSTEM (6%)

Patent ductus arteriosus, ventricular septal defect, abnormal heart, peripheral pulmonic stenosis, aortic stenosis, coarctation, absent lung lobes, vascular malformation, aortic atheromas, atrial septal defect, tetralogy of Fallot, pseudotruncus, hypoplastic aorta, abnormal pulmonary drainage, double aortic arch, cardiac myopathy

CENTRAL NERVOUS SYSTEM (3%)

Hyperreflexia, Bell palsy, central nervous system arterial malformation, Moyamoya syndrome, Arnold-Chiari malformation, stenosis of internal carotid artery, small pituitary gland, absent corpus callosum
Slow development (10%)

From Auerbach A, Buchwald M, Joenje H: Fanconi anaemia. In Vogelstein B KK, editor: The genetic basis of human cancer. *New York, 1999, McGraw Hill, p. 317–332; Shimamura A, Alter BP: Pathophysiology and management of inherited bone marrow failure syndromes.* Blood Rev *24:101–122, 2010.*
*Abnormalities are listed in the approximate order of frequency within each category.

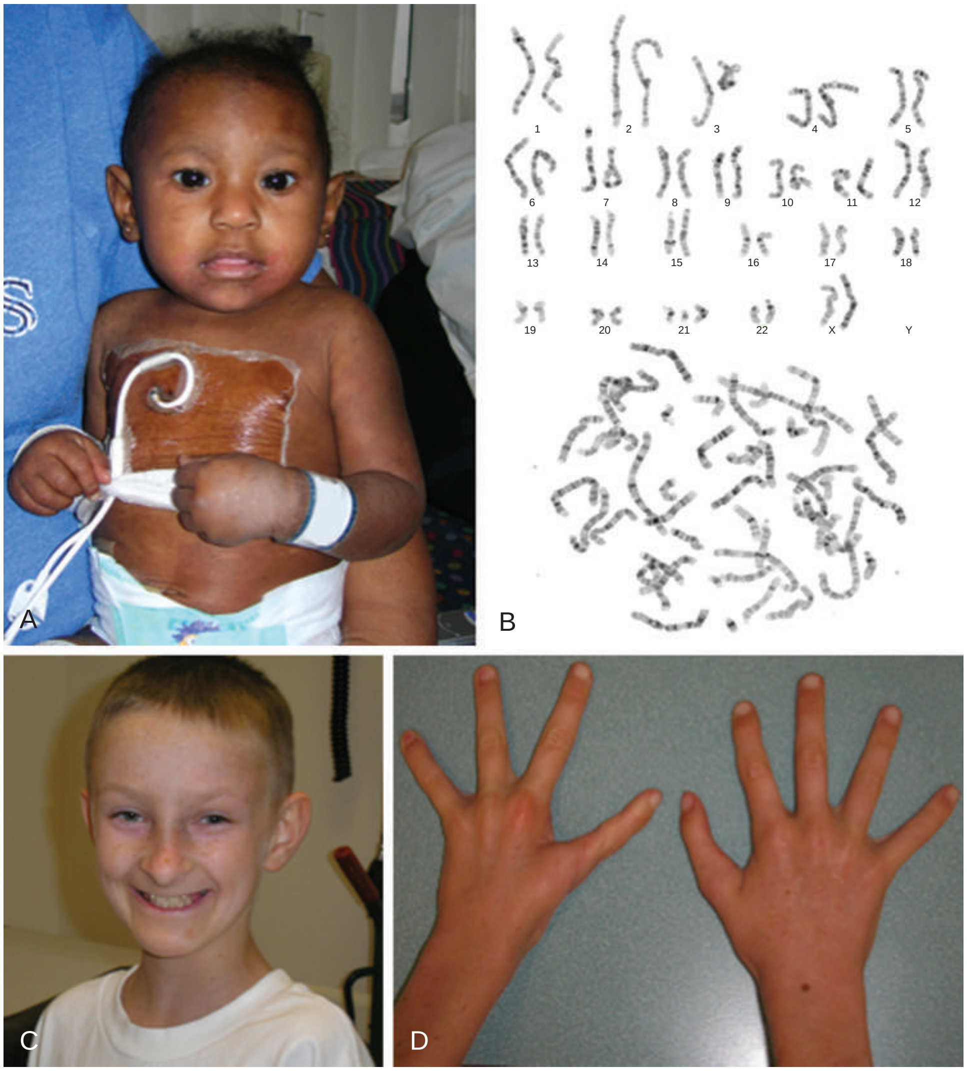

Figure 7-2 **A**, Infant female with Fanconi anemia, who exhibited several classic phenotypic features, including short stature, microcephaly, broad nasal base, epicanthal folds, micrognathia, and café-au-lait spot (left forehead). **B**, Cytogenetic findings in peripheral blood lymphocytes in Fanconi anemia. **C** and **D**, A 12-year-old boy with Fanconi anemia. Classic phenotypic features are microcephaly, broad nasal base, epicanthal folds, micrognathia, café-au-lait spot (chin and left temple), hyperpigmentation, and an absent thumb on one hand and a triphalangeal thumb on the other hand. *(B, Courtesy of Shashikanat Kulkarni, Washington University.)*

The phenotypic variability makes a diagnosis of FA difficult when it is based only on clinical features.

Endocrinopathies

Data from the International Fanconi Anemia Registry and from the Cincinnati FA cohort indicate that endocrine abnormalities are present in about 80% of children and adults with FA, primarily glucose/insulin abnormalities with a blunted first-phase insulin release, mild hypothyroidism, and male hypogonadism.[15,29-31]

Short Stature. Although short stature is an integral feature of FA,[31,32] a superimposed endocrinopathy may have an additional impact on growth and is responsive to replacement therapy.[31] Detection of an anatomic abnormality of the hypothalamic-pituitary region by magnetic resonance imaging is a diagnostic marker of permanent growth hormone deficiency.[33] In contrast to previous reports, osteopenia or osteoporosis, when adjusted for body size and height, is not frequent.[31]

Glucose Intolerance. Impaired glucose tolerance, elevated insulin levels, and overt diabetes mellitus are common in FA. Importantly, HgbA1c or elevated fructosamine does not identify glucose intolerance in FA, possibly because of the high fetal hemoglobin or abnormalities in glycosylation.[31]

Fertility. Female patients with FA usually have a shortened reproductive life because of secondary amenorrhea, irregular menses, anovulatory menstrual cycles, and premature menopause. Congenital abnormalities in the female genitourinary tract further limit fecundity. Though rare, pregnancies have been reported in women with FA. The babies born were normal, and the pregnancies seemed to have had a transient but not lasting impact on the mother's hematologic manifestations.[26,34] Pregnancy in women with FA has also been reported after BMT.[35,36] Cryptorchidism, hypogenitalism, hypergonadotropic hypogonadism, and reduced sperm counts are frequent in male patients with FA. Reports of male FA patients fathering children are rare.[26]

Hematologic Abnormalities

Progressive BMF is one of the hallmarks of FA, although the hematologic findings vary. Thrombocytopenia and macrocytosis often precede anemia and neutropenia. Elevated hemoglobin F levels[37] and elevated expression of "i" antigen on red cells usually coincide with macrocytosis and are suggestive of stress hematopoiesis.[38] Serum alpha-fetoprotein levels are consistently elevated in FA patients irrespective of the presence of liver abnormalities.[39,40] Erythropoietin levels are usually elevated in anemic FA patients. The first hematologic abnormalities in individuals with FA are detected at a median age of 7 years. The majority of FA patients already have pancytopenia at the time of diagnosis (53%). By the age of 40, the cumulative incidence of hematologic abnormalities is 90% to 98%.[19,41]

In rare cases, thrombocytopenia may be present at birth and progress to pancytopenia in the neonatal period or infancy.[16,42] Thus FA also has to be considered in cases of aplastic anemia in neonates and infants. In other patients, hematologic abnormalities never become clinically evident, and the diagnosis of FA is made later in life as a result of late FA-associated complications such as cancer or leukemia. The emergence of revertant cells leading to hematopoietic mosaicism is often associated with a mild or absent hematologic phenotype (see later). Finally, in a small proportion (2% to 5%) of FA patients, MDS or leukemia is diagnosed but the underlying BMF never becomes clinically apparent.[16] Bone marrow examination generally shows reduced cellularity; however, it may also be normocellular or hypercellular, particularly in disease that evolves into MDS or MDS/acute myeloid leukemia (AML). The cumulative incidence of BMF is approximately 50% by 40 to 50 years of age.[19,41] BMF is usually progressive. Fifty percent of individuals who are initially found to have thrombocytopenia progress to pancytopenia within 3 to 4 years.[16]

Myelodysplastic Syndrome and Acute Leukemia in Patients with Fanconi Anemia

The cumulative incidence of MDS in FA patients is approximately 30%, and of acute leukemia about 10% by the age of 40 to 50 years.[19,41] In the literature the definition of MDS and acute leukemia in FA patients varies, which makes a strict comparison difficult. Clonal hematopoiesis, as suggested by nonrandom X-inactivation, may be present even before the onset of MDS.[43,44] Clonal cytogenetic abnormalities are found in 34% to 48% of FA patients.[16] Fluctuations are frequent, including the disappearance of clones, the appearance of new clones, and clonal evolution.[45] Chromosomal abnormalities in MDS most frequently involve chromosomes 1q+, 3q+, −7/7q, 11q− 20q−, 6, 13, and 21q− (Fig. 7-3).[44,46]

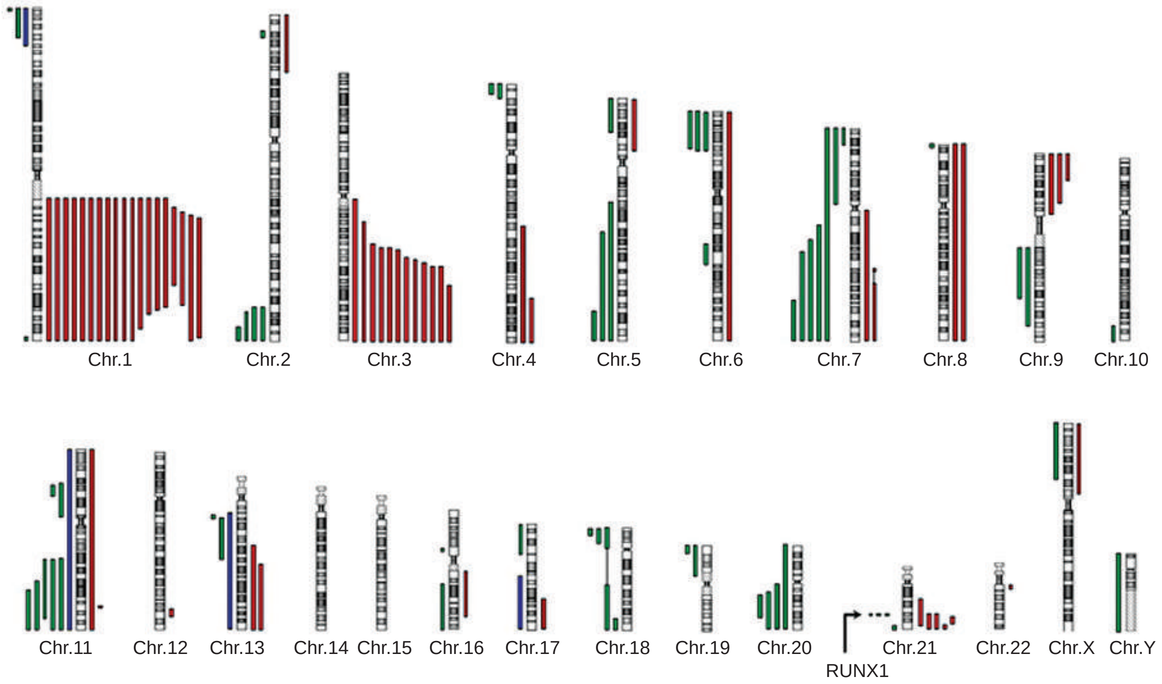

Figure 7-3 A recurrent pattern of somatic copy number abnormalities and uniparental disomy (UPD) in Fanconi anemia bone marrow cells. All acquired copy number and UPD regions found in the bone marrow cells of 57 individuals with Fanconi anemia are shown. Green lines represent deletions; red lines, gains; and blue lines, regions of UPD (somatic copy-neutral loss of heterozygosity). Constitutional copy-neutral homozygosity regions are not shown. The RUNX1 gene location at 21q22 is shown. *(From Quentin S, Cuccuini W, Ceccaldi R, et al: Myelodysplasia and leukemia of Fanconi anemia are associated with a specific pattern of genomic abnormalities that includes cryptic RUNX1/AML1 lesions.* Blood *117:e161–170, 2011.)*

Individuals in whom clonal cytogenetic abnormalities develop have a reduced survival rate of 35% to 40% as opposed to 92% in FA patients without such abnormities. An exception is patients with an isolated 1q+ that may be present without morphologic MDS and is not associated with progression to MDS/AML.[44,46] MDS morphology, as defined by dysplasia in multiple blood cell lineages, portends a poor outcome, with a 5-year survival rate of 9%. Gain of the distal portion of chromosome 3q(26-29) is frequently present in FA patients and is associated with a poor prognosis, decreased survival times, and an increased frequency of MDS/AML.[44,46-48]

Leukemia is the most common malignant disease in patients with FA.[19,41] AML is the most frequent leukemic phenotype, although patients with acute lymphocytic leukemia and chronic myelomonocytic leukemia have been described. Leukemia in patients with FA shows many molecular and clinical similarities to leukemia occurring in other IBMFSs; cases of FA-associated leukemia are notoriously difficult to treat, and most patients die within 6 months of diagnosis. Leukemia in patients with FA may arise de novo or develop from MDS. In some FA patients, AML may be the first hematologic manifestation of disease. Leukemic cells often show complex cytogenetic abnormalities, including abnormalities similar to those seen in MDS. Chromosomal translocations and mutations in oncogenes and tumor-suppressor genes frequently found in de novo AML are rare in FA MDS/AML with the exception of *RUNX1* mutations, which are seen in approximately 20% of FA patients with MDS/AML.[44] Abnormalities of chromosome 7 (monosomy, isochromosome, or other structural rearrangement), followed by abnormalities of 1q (usually duplications), are frequent in FA-associated leukemia.[44,46-48]

Predisposition to Malignancy

The risk of cancer developing is about 500 to 700 times higher than in the normal population (Table 7-2). By the age of 40 years, the cumulative incidence of solid tumors is estimated to be 26% to 30%.[41] The median age at development of cancer is 16 years, versus 68 years for the same types of cancer in the general population.[41] The risk of solid tumors and leukemia developing increases with age. Thus patients with mild hematologic and phenotypic abnormalities and the longest survival times are at the highest risk for the development of tumors or leukemia. However, with increased survival after hematopoietic stem cell transplantation (HSCT), the frequency of cancer might also increase in patients with more severe disease. The most frequent cancers occur in the neck, head, and upper esophagus, followed by the vulva, anus, and lower esophagus. Human papillomavirus (HPV), particularly HPV16, is frequently isolated from patients with FA.[49] Although the FA DNA repair pathway is involved in limiting HPV replication[49] and patients with FA are frequent carriers of HPV, the role of HPV in the pathogenesis of squamous cell cancer in patients with FA remains controversial. HPV vaccination at an early age should be considered for all patients with FA. The risk for development of squamous cell cancer of the head and neck and particularly the tongue is higher in FA patients after HSCT than in those without HSCT and correlates with the presence and severity of graft-versus-host disease.[50] Adenoma of the liver and hepatocarcinoma were found mainly in patients undergoing androgen therapy.[40] Hepatoadenomas usually regress after cessation of androgen therapy.[40]

The risk and type of cancer vary for different FA subtypes (also see the section on Risk of Malignant Disease). FA patients belonging to complementation group D1 (FA-D1) with biallelic mutations in *FANCD1/BRCA2* have a high risk for the development of malignant disease at a very young age, frequently before manifestations of BMF appear, and the cumulative risk for AML or other cancers is 97% by the age of 5.2 years. In addition, the spectrum of cancer is distinct, with medulloblastoma being the predominant malignant disease,[41,51,52] possibly because BRCA2 participates in DNA repair outside the FA pathway. An increased risk for childhood cancer with a very similar spectrum has also been found in families belonging to the FA-N subtype.[53] FANCN/PALB2 binds to BRCA2 and facilitates its binding to chromatin.[54] The interaction between these two proteins explains the similar cancer predisposition in FA individuals belonging to the FA-D1 and FA-N subgroups.

All FA cancer patients commonly have a low tolerance for DNA-damaging chemotherapeutic agents. Accordingly, chemotherapeutic regimens often need to be modified, given at low dosage, or avoided in favor of alternative or surgical approaches.

Diagnosis

The most widely used diagnostic test for FA is hypersensitivity to the clastogenic (chromosome-breaking) effect of diepoxybutane (DEB) or mitomycin C (MMC).[7,55,56] The increased spontaneous chromosomal instability of FA cells leads to distinctive chromosomal breaks and gaps and various chromatid interchanges, which were previously used as a cellular marker for FA. The frequency of spontaneous chromosomal instability in FA cells is highly variable, and it is thought to be responsible for the increased susceptibility of FA patients to cancer. The sensitivity of FA cells to the clastogenic effect has been studied for numerous cross-linking agents, but DEB and MMC are the agents most widely used for the diagnosis of FA.[7,55] Figure 7-2, *B* shows the increased spontaneous chromosome fragility in peripheral lymphocytes in a patient with FA. The diagnosis of FA is made when DEB-treated cultured lymphocytes demonstrate a 3- to 10-fold increase in chromosomal breakage over normal controls. The tests are highly sensitive and fairly specific for FA and are used for the diagnosis of FA before the development of clinical disease and for prenatal diagnosis.[7,55] Possible rare exceptions that can result in a pattern of DEB- or MMC-induced chromosomal breakage similar to that found in FA patients are individuals with specific mutations in the *NBS1* gene in Nijmegen breakage syndrome and patients with cohesinopathies, that is, those with Roberts syndrome and Warsaw breakage syndrome.[57-59] However, more frequently, the presence of revertant cells in the specimen may complicate the interpretation of DEB or MMC test results (see the section on

From Alter BP: Cancer in Fanconi anemia, 1927-2001. Cancer 97:425–440, 2003; *Alter BP, Giri N, Savage SA, et al: Malignancies and survival patterns in the National Cancer Institute inherited bone marrow failure syndromes cohort study.* Br J Haematol 150:179–188, 2010; *Kutler DI, Singh B, Satagopan J, et al: A 20-year perspective on the International Fanconi Anemia Registry (IFAR).* Blood 101:1249–1256, 2003; *Rosenberg PS, Greene MH, Alter BP: Cancer incidence in persons with Fanconi anemia.* Blood 101:822–826, 2003.

*The four cohorts are not mutually exclusive.

Somatic Mosaicism, Functional Reversion, and Attenuation of Fanconi Anemia Cells). It is estimated that 10% to 25% of FA patients exhibit two populations of phytohemagglutinin-stimulated lymphocytes, one that is sensitive to the clastogenic effects of DNA cross-linking agents and one that is resistant to them.[17,60] Thus the presence of only a few metaphases with multiple structural chromosomal changes might indicate FA with somatic mosaicism. In these cases, demonstration of increased chromosomal breakage in DEB- or

MMC-treated fibroblasts might help confirm the diagnosis of FA.

Immunoblotting for FANCD2 Monoubiquitination

Biallelic mutations in 10 of the 15 FA genes (*FANC* genes) lead to failure of FANCD2 monoubiquitination, and failure of FANCD2 monoubiquitination is specific for a defect in the FA pathway (see the section on Function of FANC Proteins). Testing for FANCD2 monoubiquitination by immunoblotting of peripheral blood lymphocytes and fibroblasts is therefore used in some laboratories as an alternative first-line tool for the diagnosis of FA.[61,62] Biallelic mutations in *FANCD1/BRCA2*, *FANCJ*, *FANCN/PALB2*, *FANCO/RAD51C*, and *FANCP/SLX4* that have normal FANCD2 monoubiquitination but an abnormal DEB or MMC test (or both) are missed with this assay and, therefore, additional testing is required.

Genetic Testing for *FANC* Gene Mutations

Only the identification of biallelic mutations in a *FANC* gene definitively confirms the diagnosis of FA. Currently genetic testing for *FANC* gene mutations is not usually recommended as a first-line tool for the diagnosis of FA. Possible exceptions are families with a known *FANC* gene mutation and FA in a population with a high frequency of a founder mutation, for example, a case of FA in Spanish gypsies. The indications, advantages, and difficulties of genetic testing for biallelic mutations in *FANC* genes are discussed later. As costs decrease, targeted or whole-genome next-generation sequencing is likely to become the diagnostic test of choice for patients clinically suspected to have FA (see the section on Molecular Diagnosis of Fanconi Anemia).

Cellular Phenotype of Fanconi Anemia Cells

In addition to increased spontaneous and induced chromosomal instability, FA cells have several other phenotypic characteristics (Table 7-3). FA cells have increased sensitivity to other DNA-damaging agents, such as ionizing radiation and oxygen radicals.[6,7,63,64] FA cells have an abnormality in cell cycle distribution, with an increased number of cells with 4N DNA content, suggesting a delay in the G_2/M or late S phase (or both) of the cell cycle.[65] FA cells have a failure in cytokinesis forming an increased number of ultrafine DNA bridges (UFB) during the M phase of the cell cycle, leading to increased chromosome instability and binucleated cells that undergo apoptosis.[66] The increase in cells with 4N DNA content is accentuated after treatment with interstrand DNA cross-linking agents. Flow cytometric measurements of the increase in the proportion of cells with 4N DNA content after such treatment may be used as an additional criterion for the diagnosis of FA.[67] However, similar results have been obtained in patients with ataxia-telangiectasia. FA cells show accelerated telomere shortening in vitro and an increase in telomere free ends and chromosome end fusions, suggesting a defect in maintenance of telomere integrity and increased breakage at telomeric sequences.[68,69] Cells deficient in the FA repair pathway are hypersensitive to both formaldehyde and acetaldehyde.[70,71,72]

TABLE 7-3 Cellular Abnormalities in Fanconi Anemia

Feature	References
Spontaneous chromosome breaks	60
Sensitivity to cross-linking agents	7, 55, 64
Sensitivity to formaldehyde	70-72, 89
Prolongation of G_2/M phase and S phase of cell cycle	67, 674
Failure in cytokinesis, with increased number of ultrafine DNA bridges (UFB) during M phase, binucleated cells	66
Accelerated telomere shortening	10, 69, 675, 676[*]
Hypersensitivity to ionizing radiation[†]	677
SENSITIVITY TO OXYGEN	Reviewed in 139

Modified from Kaddar T, Carreau M: Fanconi anemia proteins and their interacting partners: a molecular puzzle. Anemia 2012:425814, 2012.

[*] Experiments in mice suggest that accelerated telomere shorenting is not a direct effect of FA gene products on telomeres but rather an indirect effect, such as the increased sensitivity to oxygen radicals.

[†] Hypersensitivity to ionizing irradiation is controversial. More recent results suggest an increased sensitivity in the majority of fa complementation groups.

Differential Diagnosis

Clinically, FA has to be differentiated from other IBMFSs, particularly dyskeratosis congenita (DC), Diamond-Blackfan anemia (DBA), Shwachman-Diamond syndrome (SDS), Wiskott-Aldrich syndrome (WAS), thrombocytopenia with absent radii (TAR), and other nonclassified forms of BMF. Clinical manifestations, associated physical abnormalities, family history (pattern of inheritance), and increased chromosomal fragility in the DEB or MMC test performed on cultured peripheral lymphocytes or fibroblasts, or both, are helpful in strengthening the diagnosis of FA. However, only identification of pathogenic mutations on both copies of an FA gene (biallelic mutation) may definitely consolidate the diagnosis of FA. Congenital abnormities in FA may have an overlap with malformations seen in other disorders with genetic and nongenetic causes. Thrombocytopenia and radial ray abnormalities are also characteristic of TAR. However, in FA, if the radii are affected, the thumbs are always abnormal; in TAR, in which the radii are absent, thumbs are always present. Other syndromes that have phenotypic overlap with FA include Holt-Oram syndrome (MIM 142900), which is characterized by thumb anomalies and atrial septal defects and caused by mutations in the *TBX5* gene, and Baller-Gerold syndrome (MIM 218600) and Rothmund-Thomson syndrome (MIM 278400), which are caused by mutations in the *RECQL4* gene and characterized by radial defects, craniosynostosis, and cancer predisposition but not BMF. FA patients may present with VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia) or VACTERL (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis and dysplasia, and limb defects) (MIM 192350) or the IVIC syndrome (MIM 147750), which is an acronym for Instituto Venezolano de Investigaciones Cientificas, the institution at which a family with autosomal dominant radial ray defects, hearing impairment, internal ophthalmoplegia, and thrombocytopenia was first described. In patients presenting with these associated anomalies, FA should be excluded.

The increased chromosomal breakage in FA has to be distinguished from that seen in Bloom syndrome (MIM 210900), another single-gene disorder with a predisposition for leukemia as a result of mutation in the helicase RecQ protein-like-3 gene (*RECQL3*). Chromosomal aberrations are in general more numerous in FA cells than in Bloom cells. Furthermore, in Bloom syndrome, most interchanges occur between homologous chromosomes, whereas in FA they are more frequently seen between nonhomologous chromosomes.

Nijmegen breakage syndrome (NBS; MIM 251260), caused by mutations in the *NBS1* gene and characterized by immunodeficiency and a predisposition to lymphoma, is another autosomal recessive chromosomal breakage disease. A small number of patients with NBS may have FA-like features, including BMF and the development of myeloid leukemia,[73,74] and specific mutations in the *NSB1* gene cause an increased clastogenic response to MMC and DEB testing.

A third disease associated with spontaneous chromosomal breakage and hematopoietic malignant disease is ataxia-telangiectasia (MIM 208900), which is inherited in an autosomal recessive manner. Cells from patients with ataxia-telangiectasia are hypersensitive to ionizing radiation but not to cross-linking agents. Furthermore, the disease is associated with immunodeficiency and progressive cerebellar neuronal degeneration, which clearly distinguish this condition from FA.

Seckel syndrome (*SCKL1*, MIM 210600), caused by a defect in the signaling pathway dependent on ataxia-telangiectasia and Rad3-related (ATR), may have some clinical similarities to FA, including anemia and an increased risk for AML.

Patients deficient in DNA ligase IV (*LIG4,* MIM 606593) are characterized by microcephaly, growth retardation starting in utero, distinctive facial appearance (birdlike face), developmental delay, immunodeficiency, pancytopenia, and pronounced clinical and cellular radiosensitivity. LIG4 deficiency is another rare IBMFS caused by defective DNA repair.[75,76]

Two of the cohesinopathies, Roberts syndrome (MIM 268300) (caused by mutations in *ESCO2,* encoding an acetyltransferase involved in sister chromatid cohesion) and Warsaw breakage syndrome (MIM 613398) (caused by mutations in *DDX11/ChlR1,* encoding an XPD-like DNA helicase), show excessive MMC-induced chromosomal breakage in primary lymphocyte cultures and an increased arrest of primary skin fibroblasts in the G_2/M phase of the cell cycle that need to be distinguished from FA.[59]

Genetic Characteristics

Inheritance. FA is a genetically heterogeneous recessive disorder. Mutations in at least 15 different genes, all of which have been identified, may be responsible for FA. Inheritance of FA is autosomal or, in rare cases, X-linked.

Complementation Groups. At least 16 genetic subtypes or complementation groups have been identified (FA-A, FA-B, etc.), each with a distinctive disease gene (Fanconi anemia gene A [*FANCA*], *FANCB*, etc.). The majority of patients belong to complementation group A (≈ 60% to 70%), followed by complementation groups C and G. Table 7-4 shows the complementation groups and the genes responsible for FA and their frequency. Complementation groups were originally defined by somatic cell fusion and the ability of the heterokaryon to correct the MMC hypersensitivity as measured in a growth inhibition assay.[77,78] Correction of the MMC hypersensitivity indicates that the two fusion partners belong to different complementation groups, whereas no correction indicates that they belong to the same complementation group. More recently and as more *FANC* genes are identified, complementation groups are assigned through the correction of MMC hypersensitivity after introduction of the respective wild-type cDNA (complementation by cDNA expression). Retroviruses expressing *FANC* cDNA may be used to correct the phenotype of T cells from FA patients, which determines the complementation group in a rapid, accurate manner.[79]

Fanconi Genes (*FANC* Genes). *FANC* genes have been identified by expression cloning, positional cloning, protein complex purification, or a combination thereof and are summarized in Table 7-4. Figure 7-4 schematically represents the 15 *FANC* genes and their functional domains.

Function of FANC Proteins. The FANC proteins have been shown to act mainly during the S phase of the cell cycle. Their main role is in the repair of DNA interstrand cross-links that impede replication and transcription by inhibiting DNA strand separation.[80-82] It is generally thought that FANC proteins sense, promote, and coordinate three DNA repair pathways: Repair is initiated by recognition of a lesion by nucleotide excision repair components, followed by incisions made flanking the interstrand cross-links; the gapped intermediate that is produced is filled by translesion synthesis or by repair of broken replication forks by homologous recombination.[83]

TABLE 7-4 Complementation Groups and Genes Responsible for Fanconi Anemia

Complementation Group	Responsible Gene	Percentage of FA Patients	Locus	Protein (kDa)	FANCD2 Monoubiquitination	Main Function of Protein	Comments	References
FA-A	*FANCA*	≈66	16q24.3	163	+	FA core complex	Phosphorylated following DNA damage	697
FA-B	*FANCB*	≈2	Xp22.31	95	+	FA core complex		121
FA-C	*FANCC*	≈10-15	9q22.3	63	+	FA core complex		698
FA-D1	*FANCD1/BRCA2*	3-4	13q12-13	380	–	Recruits RAD51 and promotes HR repair		699
FA-D2	*FANCD2*	≈3	3p25.3	155, 162	+	Monoubiquitinates and recruits FANCP to chromatin	Phosphorylated and monoubiquitinated following DNA damage	700
FA-E	*FANCE*	2-3	6p21.3	60	+	FA core complex, probable adaptor for FANCD2	Direct binding to FANCD2, phosphorylated following DNA damage	701
FA-F	*FANCF*	≈2	11p15	42	+	FA core complex		702
FA-G	*FANCG/XRCC9*	8-10	9p13	70	+	FA core complex		703
FA-I	*FANCI*	<2	15q25-26	150	+	Monoubiquitinated protein (part of FANCI-FAND2 subcomplex)	Phosphorylated and monoubiquitinated following DNA damage, binds to FACND2	448, 704-706
FA-J	*FANCJ/BACH1/Brip1*	<2	17q22.3	150	–	5′→3′ DNA helicase/ATPase	Binding to BRCA1	707
FA-L	*FANCL/PHF9/POG/FAAP43*	Rare	2p16.1	43	+	FA core complex, ubiquitin ligase	Recruits UBE2T, monoubiquitinates FANCD2 and FANCI	708
FA-M	*FANCM/ Hef/ FAAP250*	Rare	14q21.3	250	+	FA core complex, branch migration/ATPase activity, sensor for DNA cross-link damage	Helicase/nuclease motif, phosphorylated following DNA damage, interacts with BLM	709
FA-N	*FANCN/PALB2*	Rare	16p12.1	130	–	Mediates interaction between BRCA1 and BRCA2 during HR	Binding to BRCA2	54, 108, 710
FA-O	*FANCO (RAD51C)*	Rare	17q22	43	–	Promotes HR, interacts with RAD51 and RAD51 homologues		711
FA-P	*FANCP (SLX4)*	Rare	16p13.3	200	–	Functions as holiday junction resolvase with SLX1	Interacts with XPF-ERCC1 and EME1-MUS81 nucleases	712

Figure 7-4 Schematic representation of the Fanconi anemia genes and their functional domains. *BTB/POZ*, Broad-complex, tramtrack, and bric-a-brac/poxvirus and zinc finger; *CCD*, conserved C-terminal domain; *dsDNA*, double-stranded DNA; *MLR*, MEI9^{XPF}-interaction–like region; *NES*, nuclear export sequence; *NLS*, nuclear localization signal; *OB*, oligonucleotide/oliosaccharide-binding fold; *ssDNA*, single-stranded DNA; *TD*, tower domain; *TRP*, tetratricopeptide repeat; *UBZ*, ubiquitin-binding zinc-finger domain. *(Modified from Taniguchi T, D'Andrea AD: Molecular pathogenesis of Fanconi anemia: recent progress.* Blood *107:4223–4233, 2006.)*

Thus it is thought, and schematically summarized in Figure 7-5, that in normal cells the FA pathway serves to minimize the severity of mutational outcomes by favoring error-free DNA repair and error-prone DNA repair that results in base pair substitutions or small deletions over DNA repair that results in larger deletions and chromosomal rearrangements (Box 7-4 summarizes the main DNA repair pathways).[84,85]

The current model suggests that FANCM recognizes the DNA interstrand cross-links and initiates DNA repair by recruiting eight FA core complex proteins (FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL, and FANCM) to the DNA damage site, stabilizing the stalled replication fork, and initiating ATR mediated checkpoint signaling. The FA core complex functions as an ubiquitin ligase, of which FANCL is the catalytic subunit. FANCE recruits FANCD2 to the FA core complex, whereas disease-associated *FANCE* mutations disrupt the FANCE-FANCD2 interaction.[86] Figure 7-6 schematically summarizes the current view of the FANC protein interconnections in the FA DNA repair pathway.[80-82,87] During activation, multiple FA proteins undergo phosphorylation by ATR-CHK1 checkpoint kinases, highlighting the close interconnection of the FA pathway with DNA damage response signaling. The FA core complex catalyzes monoubiquitination of the FANCI-FANCD2 complex, which is a key regulator of the FA pathway. A defect in any of these core proteins results in failure to monoubiquitinate the FANCI-FANCD2 complex, underscoring the importance of this modification in the FA pathway. FANCI and FANCD2 are dependent on each other for their respective monoubiquitination. The FANCL subunit is a ubiquitin E3 ligase, and in concert with the UBE2T E2 enzyme, it conjugates a single ubiquitin to FANCD2 and to FANCI. The monoubiquitinated FANCI-FANCD2 complex is relocalized to the DNA lesion, where it coordinates cross-link repair together with downstream FA proteins. Monoubiquitinated FANCD2 acts as a platform to recruit multiple nucleases, including FANCP, to coordinate nucleolytic incisions flanking the interstrand cross-links. The incision creates a DSB, which is repaired by homologous recombination. Downstream FA proteins, including FANCD1, FANCJ, FANCN, and FANCO, promote

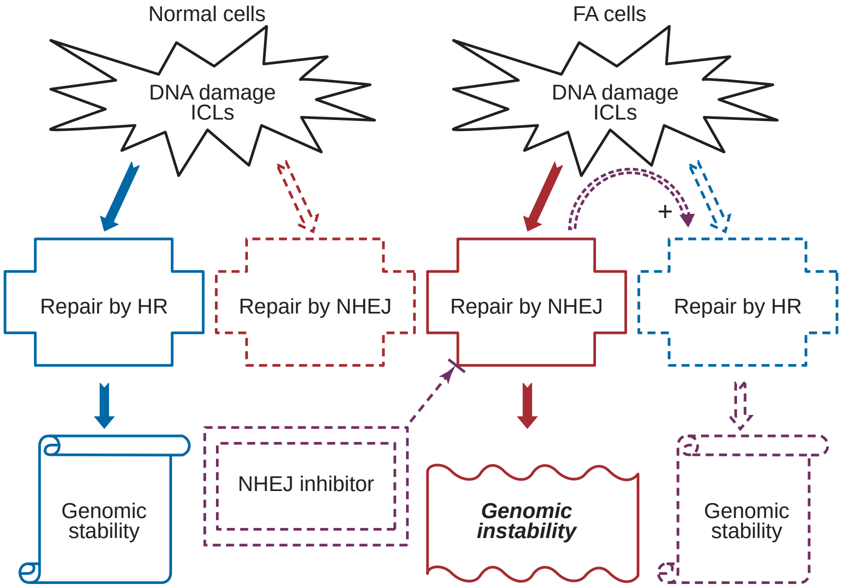

Figure 7-5 Presumed function of the Fanconi anemia DNA repair pathway. In normal cells the Fanconi anemia pathway ensures correct DNA repair by homologous recombination, whereas error-prone alternative pathways using nonhomologous end joining are rarely used. In Fanconi anemia cells the error-free DNA repair by homologous recombination is impaired, so alternative DNA repair pathways are used more frequently, leading to genomic instability and cell death. Suppression of nonhomologous end joining by deleting a component of this pathway or by using DNA-dependent protein kinase catalytic subunit inhibitors promotes the repair of the double-strand breaks by FA-independent pathways of homologous recombination and improves in some experimental systems the sensitivity to DNA cross-linking agents *(dashed arrow). HR,* Homologous recombination; *ICLs,* intrastrand cross-links; *NHEJ,* non-homologous end joining. *(Modified from Deans AJ, West SC: DNA interstrand crosslink repair and cancer.* Nat Rev Cancer *11:467–480, 2011.)*

RAD51-dependent strand invasion and the resolution of homologous recombination intermediates.

The FA core complex is assembled sequentially from subcomplexes, which may have additional functions aside from DNA repair. Several FA proteins, including FANCA, FANCE, FANCG, FANCD2, FANCI, and FANCM, are posttranslationally modified by phosphorylation, and two FA proteins, FANCC and FANCD2, are regulated through a caspase-mediated proteolytic process. FANC proteins have been reported to interact with a number of other proteins, including proteins involved in transcription, the cell cycle, oxidative metabolism, cell signaling, and cytokine response, suggesting that FANC proteins/subcomplexes might have a separate role in cell cycle control, apoptosis, hematopoiesis, and tumorigenesis that is independent of DNA damage recognition/repair.[88]

Bone Marrow Failure in Fanconi Anemia

Although the impairment of DNA repair seems to explain the genomic instability and possibly the increased risk for malignant disease in patients with FA, its link to the pathogenesis of BMF is less obvious, because mutations associated with genomic instability outside the FA DNA repair pathway are not usually associated with BMF. There is an ongoing debate on whether BMF is a direct consequence of the FA DNA repair defect or is caused by impairment of functions apart from DNA repair. Naturally, FA DNA repair and non–DNA repair pathways in the pathogenesis of BMF may not be mutually exclusive but, rather, may overlap. However, two recent findings point strongly towards defective DNA repair being at least the initiating cause of BMF in FA. In a recent study Ceccaldi and colleagues[4] demonstrated that the basal and MMC-induced levels of p53 and its downstream target p21 are elevated in the blood, bone marrow, and liver of fetuses with FA, with a simultaneous accumulation of cells in phase G_0/G_1. These findings suggest that in FA patients the pool of available hematopoietic stem cells and progenitor cells is compromised, with fewer cells and less proliferation of cells than in normal individuals. The impairment is intrinsic, occurs even in the fetus, and leads to overt BMF later in life.[4] Although cross-linking agents have been used experimentally to

Box 7-4 **DNA Repair Pathways**

DNA repair pathways are highly regulated pathways that involve detection of DNA lesions, signaling to recruit DNA repair factors, activation of DNA repair enzymes, and disassembly or degradation of DNA repair factors after repair.

- EXCISION OF DAMAGED AND MISMATCHED BASES
  - Nucleotide excision repair, including global genome repair and transcription-coupled repair
  - Base pair excision repair
  - Mismatch repair
- REPAIR OF DOUBLE-STRANDED BREAKS
  - Homologous recombination (generally error free)
  - Nonhomologous end joining (generally error prone)
- DNA STRESS REPLICATION PATHWAY, REPLICATION PATHWAY OF DAMAGED TEMPLATES DURING DNA SYNTHESIS
  - Translesion DNA synthesis (error prone)

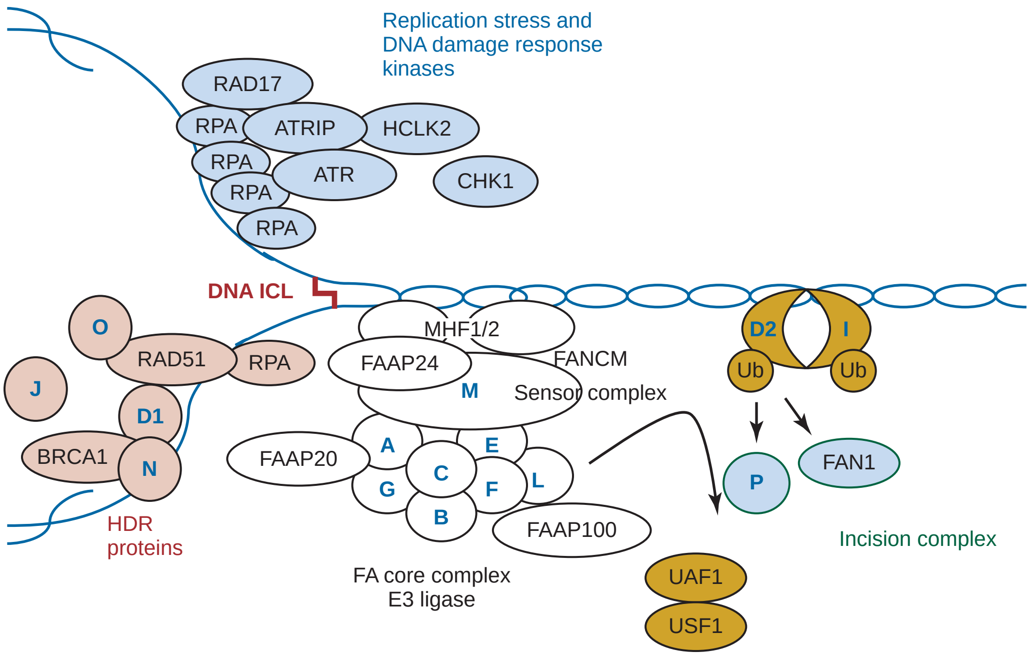

Figure 7-6 Schematic overview of protein interconnections in the Fanconi anemia DNA repair pathway (see also text). The Fanconi anemia pathway maintains genomic stability in response to stalled replication forks, particularly in the context of interstrand DNA cross-links (DNA ICL). Fork stalling is detected by the FANCM sensor complex and triggers ATR (ataxia-telangiectasia and rad3-related)–mediated checkpoint signaling, resulting in the phosphorylation of several Fanconi anemia proteins. FANCM becomes a platform for the other Fanconi anemia core complex proteins, including the FANCL E3 ubiquitin ligase. The core complex monoubiquinates FANCD2 and FANCI (Ub) to promote interstrand DNA cross-link repair. The incision complex, including FANCP/SLX, is essential for resolving the cross-link. Repair and replication fork restart is further accomplished using translesion synthesis and homology-directed repair, which involves BRCA2/FANCD1, PALB2/FANCN, and RAD51C/FANCO. The USP1-UAF1 DUB complex removes monoubiquitin from FANCD2-I and completes the repair. *(Modified from Kee Y, D'Andrea AD: Molecular pathogenesis and clinical management of Fanconi anemia.* J Clin Invest *122:3799–3806, 2012; and Hays LE, Meyer S, van de Vrugt HJ: A molecular, genetic, and diagnostic spotlight on Fanconi anemia.* Anemia *2012:650730, 2012. demonstrate the FA defect in DNA repair, experiments by Ridpath and colleagues[70] and Langevin and colleagues[71] suggest that naturally occurring aldehydes might be a major source of endogenous cross-linking and FA pathway activation under steady-state conditions in vivo. Interestingly, HSCs express aldehyde hydrogenase type 2 (*Aldh2*), a condition that is essential for the protection of HSCs against acetaldehyde toxicity.[89] The experiments were performed in mice and need to be confirmed in patients with FA, but the findings suggest that the FA pathway is needed to protect HSCs from aldehyde-mediated genotoxicity (see the section on Mouse Models for Fanconi Anemia). Moreover, these observations explain the tissue specificity of HSC and solve the conundrum of why HSC is affected in FA but is not affected, or not to the same extent, in other non-FA DNA repair disorders.

FANC Gene Mutations in Fanconi Anemia

Detailed information on mutations identified in the *FANC* genes in patients with FA is maintained in the FA Mutation Database at Rockefeller University through the International Fanconi Anemia Registry (available at rockefeller.edu/fanconi/[19,90]) and in the Leiden Open Variation Database; chromium.liacs.nl/lovd/[91]). Frequent FA mutations and mutations with founder effects are presented in Table 7-5.

FANCA is the gene most frequently mutated in FA patients. The mutations are spread throughout the gene and include missense and nonsense mutations, small deletions, insertions, and duplications, as well as splicing mutations.[92] Of note is the substantial number of large genomic, usually intragenic DNA deletions, which account for about 40% of all pathogenic mutations within the *FANCA* gene and are thought to be due to the frequent occurrence of Alu repeats in this genomic region. Large gene deletions are not generally detected by routine nucleotide sequence–based mutation detection methods but require more specialized analysis (haplotype analysis) or molecular methods specifically designed for the detection of large gene deletions. Two small deletions (deletion of three nucleotides between positions 3788 and 3790, with c.3788_3790delTCT leading to deletion of phenylalanine at position 1263, 1263delF, and a 4–base pair (bp) deletion at position 1115, c.1115-1118delTTGG, leading to a frameshift and premature stop codon) are the most common pathogenic mutations in the *FANCA* gene, with a frequency of 8.8% and 5.5% in the

TABLE 7-5 Frequent *FANC* Gene Variants and Mutations with Founder Effect Identified in Fanconi Anemia Patients

Gene	Founder Effect	Variation at DNALevel (Old Nomenclature)[*]	Variation at Protein Level[*]	Frequency within Mutated FA Allele	Population with Founder Effect (% of All FA Patients)	References
FANCA	Yes	c.3788_3790delTCT[†]	p.1263delF	8.8%	51% Brazilians, relatively mild	90, 713
	No	c.1115-1118delTTGG[†]	p.V372fs	5.5%	2.2% Brazilians	90
	Yes	Intragenic deletion of exons 12-31, intragenic deletion of exons 17-31	del		60% Afrikaner in South Africa	714
	Yes	c.295C→T	p.Q55X		Spanish Gypsies (highest prevalence of mutant *FANCA* allele)	10
	Yes	c.65G→A	W22X		Unique to Ashkenazi Jews	715
FANCC	Yes	c.711 +4A→T (IVS4+4A→T)	Splicing		Homozygous in 80% of Ashkenazi-Jewish FA (carrier frequency 1/100), relatively common in Japan; severe phenotype in Jews, milder in Japanese	715-718
	Yes	c.67delG (322delG)	fs		Homozygous in 50% of Dutch FA patients, relatively mild phenotype	18, 716, 719
FANCG	Yes	c.1077-2A→G	Splicing		Portuguese Brazilians	94, 720, 721
	Yes	c.1480+1G→C	Splicing		French Acadians	721

[§] Associated with brain tumors.

non-Brazilian and 51.1% and 2.2% in the Brazilian mutated *FANCA* alleles (see Table 7-5).

Mutations in *FANCC* genes account for 10% to 15% of all FA cases. The splicing mutation c.711+4A→T (old nomenclature, IVS4+4A→T) in the *FANCC* gene accounts for the majority (80%) of FA cases in Ashkenazi Jewish families. Mutations in *FANCG* are responsible for about 8% to 9% of patients with FA. Several mutations with founder effects have been identified in specific populations (see Table 7-5).

Biallelic mutations in *BRCA2* are found in individuals with FA-D1. Biallelic *FANCD1/BRCA2* mutations account for about 3% to 4% of all FA patients. The majority of *FANCD1/BRCA2* mutations in FA lead to frameshifts or truncations (see Table 7-5). Interestingly, however, FA-D1 cells are not biallelic for *FANCD1/BRCA2* null alleles but have at least one hypomorphic *FANCD1/BRCA2* allele expressing a FANCD1/BRCA2 protein with some residual activity. Biallelic null *FANCD1/BRCA2* mutations have never been identified and in mice are embryonically lethal. Biallelic mutations in *FANCD1/BRCA2* have a very high risk of early malignant disease. The splice-site mutations c.859+1G→A (IVS7+1G→A) and c.859+1G→A (IVS7+1G→A) are associated with a high frequency of leukemia at a very young age,[93] whereas the frameshift mutations c.886delGT and c.6174delT are associated with brain tumors.[52]

Mutation in *FANCD2* accounts for 3% to 6% of FA-affected patients. Malformations are frequent in these patients, and hematologic manifestations appear early and progress rapidly. Although hypomorphic mutations exist, patients with *FANCD2* mutations have a relatively severe form of FA. Mutation analysis revealed 66 mutated alleles, 34 causing aberrant splicing. Many mutations are recurrent and have ethnic associations and shared allelic haplotypes. There were no biallelic null mutations, suggesting that in contrast to the *Fancd2* knockout mouse, complete absence of FANCD2 does not exist in patients with *FANCD2* mutations.[52,94]

Mutations in *FANCN/PALB2* were identified in families with the new subtype FA-N and cancer in early childhood. Similar to biallelic *BRCA2* mutations, biallelic *FANCN/PALB2* mutations confer a high risk for childhood cancer.[53,54]

Molecular Diagnosis of Fanconi Anemia

Molecular diagnosis is not routinely performed for FA, because it is expensive, labor intensive, and, in some cases, possible only in specialized laboratories using research tests that are currently not approved by Clinical Laboratory Improvement Amendments. However, only identification of biallelic mutations in a *FANC* gene (or hemizygosity for a mutation in the *FANCB* gene) definitively establishes the diagnosis of FA. Furthermore, molecular diagnostic testing enables the identification of mutation carriers, facilitates prenatal diagnosis for an existing pregnancy, and allows preimplantation genetic diagnosis for partners identified as mutation carriers.[95] For a definition of preimplantation genetic diagnosis see Box 7-5. In addition, because the clinical manifestations and severity of disease may vary depending on the affected *FANC* gene and the nature of individual mutations, molecular diagnostic testing may influence medical management not only for FA individuals carrying biallelic *FANC* gene mutations but possibly also for heterozygous *FANC* gene mutation carriers (see the section on Heterozygous Carriers of *FANC* Gene Mutations). Currently, an educated candidate gene approach is used to identify the affected *FANC* gene by taking into account the origin and ethnicity of the affected FA individual.[92,96] After exclusion of the most frequent mutations, it might be necessary to determine the complementation group and perform mutational screening of the entire coding sequence, including methods that will detect large deletions in compound heterozygotes. Protein expression analysis and functional assays are used to test for the pathogenicity of unclassified variants.[97] Multiplexed next-generation sequencing with massively parallel sequencing is becoming increasingly available for clinical genetic testing and has been shown to be an effective molecular diagnostics approach for FA.[27,98,99,100-103,104] With the decreasing costs of next-generation sequencing, customized targeted, whole-exome, or whole-genome sequencing is likely to become the future diagnostic standard for patients with FA, enabling genetic molecular diagnosis to be performed at a reasonable price in a short turnaround time (Box 7-6). Although genetic mutation analysis is likely to be successful in the majority of FA patients, in some, the responsible gene mutations might remain unclear. In addition to the large number of mutations in *FANC* genes associated with FA, a number of nonpathogenic mutations and mutations of unknown

Box 7-5 Preimplantation Genetic Diagnosis

Preimplantation genetic diagnosis (PGD) is the genetic diagnosis of a preimplantion embryo (typically on day 3 of embryo development at the 8-cell stage or on day 5 as a blastocyst) obtained by in vitro fertilization. It is usually performed in families with a severe genetic disorder or for selection of a human leukocyte antigen–compatible donor for a sibling in need of a hematopoietic stem cell transplant. The procedure is often successful but is ethically controversial.[95,100,103]

Box 7-6 Next-Generation Sequencing

DNA sequencing determines the order of the nucleotide bases (adenine, guanine, cytosine, thymine) in a molecule of DNA. Next-generation sequencing is a high-throughput technology that uses massively parallel sequencing, producing thousands or millions of sequences at once. Next-generation sequencing reduces the turnaround time and number of assays and significantly reduces the cost of analysis. In the future, next-generation sequencing will allow simultaneous screening for mutations in most or all of the loci associated with inherited bone marrow failure syndromes at once as well as screen the whole genome for the detection of novel mutations. With decreasing costs, next-generation sequencing is likely to become the diagnostic test of choice for all patients clinically suspected to have an inherited bone marrow failure syndrome or presenting with bone marrow failure in general.[104]

pathogenic significance are identified and require further functional investigations. The multitude of FA complementation groups, the presence of pseudogenes, the heterogeneity of the mutation spectrum, and the frequency of large intragenic deletions present a considerable challenge for the current and future molecular diagnosis of FA.

Heterozygous Carriers of *FANC* Gene Mutations

Heterozygous carriers of *FANC* gene mutations are not at risk for the development of BMF. Similarly, cell lines heterozygous for *FANC* gene mutations do not show the chromosomal instability (either spontaneously or in response to cross-linking agents) characteristic of FA cells with biallelic *FANC* gene mutations. However, an increased frequency of skeletal and genitourinary abnormalities[105] and an increased risk of malignant disease have been reported in heterozygous *FANC D1/J/N/O* and possibly *FANCP* and female *FANCB* gene mutation carriers.[105]

Risk of Malignant Disease in Heterozygous Carriers. A strong association exists between heterozygous mutation of *FANC* genes and susceptibility to breast or ovarian cancer,[106] and other forms of malignant disease have been identified in heterozygous mutation carriers. Carriers of mutations in *BRCA1* or *BRCA2/FANCD1* have a 65% and 35% risk, respectively, of developing breast cancer and a 39% (*BRCA1*) and 6% (*BRCA2/FANCD1*) risk for ovarian cancer.[107] Heterozygous *BRCA2/FANCD1* mutations additionally predispose to pancreatic, prostate, and gastric cancers, as well as melanoma. Monoallelic truncating *FANCN/PALB2* mutations are associated with familial breast cancer, although the risk of breast cancer is lower (2.3-fold) than that in *BRCA2* mutation carriers.[108] Heterozygosity for *FANCJ* mutations has been identified in patients with early-onset breast cancer.[109] Monoallelic pathogenic mutations in *RAD51C/FANCO* confer an increased risk for breast and ovarian cancers.[110] Heterozygous germline mutations in *FANCC* and *FANCG* and loss of heterozygosity or functional biallelic loss in the tumor sample have been identified in rare patients with pancreatic cancer.[111] Furthermore, heterozygous germline mutations of *FANCA* have been identified in a small percentage of patients with AML.[112]

Somatic *FANC* Gene Mutations in Cancer

Cancer cells often accumulate a large number of mutations within an individual cancer cell, many of which promote cell growth and survival. It is therefore thought that a cancer cell with an increased mutation rate, a mutator phenotype, will have a selective advantage in tumor growth and development. Inactivation or mutation of genes involved in maintaining genetic stability is thought to be an early event in cancer development. The FA pathway has been observed to be one of the pathways that maintains genomic stability and is targeted in several forms of sporadic cancer.[113,114]

Identification of acquired abnormalities in the FA pathway might become clinically important because these tumors are expected to have increased sensitivity to cross-linking agents such as cisplatin, cyclophosphamide, MMC, and other novel agents.[115] Thus identification of abnormalities in the FA pathway may serve as a biomarker that identifies a subgroup of patients with cancers selectively sensitive to specific chemotherapeutic agents. Similarly, inhibition of the FA pathway in cancer may render cancer cells sensitive to chemotherapy.[113,116,117]

Genotype-Phenotype Correlation

Clinical findings in FA are highly variable, although within an individual family the presence or absence of multiple congenital abnormalities or the age at onset of other disease manifestations is usually concordant.[21] More recent studies have demonstrated that disease severity and manifestations are determined, at least in part, by the *FANC* gene affected (complementation group) and by the nature of the mutations.[14,19,118] For example, patients with mutations in the *FANCA* gene usually have a milder form of disease and BMF develops at a later age than it does in FA individuals with mutations in the *FANCC* or *FANCG* gene,[18] whereas in FA patients with biallelic *FANCD1* or *FANCN* mutations, cancer develops even before the manifestation of BMF.[51,53,119,120] Furthermore, splice-site mutations in *FANCD1* are more frequently associated with the development of leukemia,[52,120] whereas frameshift mutations within the same gene more frequently lead to brain tumors (see the section on *FANC* Gene Mutations in Fanconi Anemia).[51,52,119] Malformations are frequent in *FANCD2* patients, and hematologic manifestations appear earlier and progress more rapidly than they do in non-*FANCD2* patients.[94]

FA-B is X-linked, in contrast to all other forms of FA, which are autosomal. Thus a single mutation is sufficient to cause a phenotype and disease in males. In females, because of inactivation of one of the two X chromosomes, a phenotype is expressed only in cells with the *FANCB* mutation on the active X chromosome. Because X-chromosome inactivation occurs at random in early embryogenesis and, once determined, persists clonally, one might expect female *FANCB* mutation carriers to have a mild form of FA-B. Interestingly, however, to date no female FA-B patient with clinical manifestations of FA has been reported, and careful clinical examination of females heterozygous for *FANCB* gene mutations showed no manifestations of disease. Molecular studies investigating X-inactivation revealed that only the X chromosome with the normal *FANCB* gene is expressed in blood and bone marrow and also in fibroblasts.[121] This finding indicates a proliferative disadvantage of cells expressing the mutant *FANCB* allele and complete outgrowth by phenotypically normal cells, not only in bone marrow but possibly also in all other tissues. This situation differs from other X-linked IBMFSs such as X-linked DC (see the section on Dyskeratosis Congenita). For individuals carrying a *FANCB* mutation, however, longer follow-up and examination of additional mutation carriers will be necessary to determine whether some FA-B cells persist in female carriers and whether

Box 7-7 Genetic Mosaicism

Genetic mosaicism is defined as the presence of two or more genetically distinct populations of cells in a single individual that differ from each other at the DNA sequence level but are derived from a single zygote. In Fanconi anemia, genetic mosaicism results from reversion, which is the genetic correction of the *FANC* mutation.[126]

these persisting FA-B cells are at risk for malignant transformation. Whether somatic *FANCB* inactivation can be found in malignant disease (only a single mutation on the active X chromosome is required) remains to be determined.

Somatic Mosaicism, Functional Reversion, and Attenuation of Fanconi Anemia Cells

About 10% to 25% of FA patients have been found to have mosaicism in the peripheral blood inasmuch as two populations of lymphocytes can be detected, one with the classic increased sensitivity to cross-linking agents characteristic of FA cells and the other usually a slowly increasing second population that is resistant to treatment with these agents.[17] For a definition of genetic mosaicism see Box 7-7. The presence of mosaicism is usually considered if the clinical course of the disease is milder than expected in comparison with individuals with the same genetic abnormality, if the course of the disease improves spontaneously rather than worsens, or in the presence of classic phenotypic abnormalities but rather mild or absent hematologic disease. The molecular mechanisms of genetic reversion include intragenic recombination (in compound heterozygotes), mitotic gene conversion (nonreciprocal exchange of genetic information as a result of heteroduplex formation between nonsister chromatids),[22] DNA slippage, second-site compensating mutations,[122,123] and site-specific correction by an as yet unknown mechanism.[22] Gene reversion may occur in vivo or in vitro. In FA patients the reverting mutation is thought to occur in progenitor cells with self-renewing capability,[124] possibly stem cells, thereby conferring a proliferative advantage to the revertant cells; this may lead to expansion of the revertant clone and progressive replacement of the FA cells in bone marrow.[17,125,126] Genetic reversion in FA has been documented to date only in hematopoietic cells, not in fibroblasts.[122,123] However, the fact that females heterozygous for *FANCB* mutations have biased X-inactivation in fibroblasts suggests that an intact FA pathway confers a proliferative advantage to nonhematopoietic cells. Thus the frequency of genetic reversion is largely unknown and so are its clinical consequences. In many patients genetic reversion is associated with hematologic improvement.[17,123] However, genetic reversion has also been found in leukemic cells from FA patients,[127] indicating that genetic reversion may confer a selective growth advantage and resistance of leukemic or preleukemic cells to specific chemotherapy drugs. Furthermore, genetic reversion in hematopoietic cells has no effect on cancer frequency in nonhematopoietic tissues. The strong selection for a functional FANC pathway may be used to advantage in gene therapy approaches. Genetic mosaicism is responsible at least in part for phenotypic variability, particularly within an individual family, and may create difficulty in interpretation of the chromosomal breakage testing with DEB and MMC (see the section on Diagnosis) or even lead to false-negative testing results.[128] DEB or MMC testing of fibroblasts should therefore be considered in patients with clinical or genetic suspicion of FA but a negative DEB or MMC test result for peripheral blood lymphocytes.

The term *attenuation* has been introduced by Ceccaldi and associates[4] for FA patients whose peripheral blood cells lack monoubiquitination of FANCD2 and have the characteristic increased chromosomal breaks after MMC treatment but whose cells, unlike those of most patients, do not show the characteristic G_2 arrest after MMC treatment. Most of these patients developed MDS or leukemia later in life. Attenuation was accompanied by clonal hematopoiesis, implying that all of the peripheral blood cells were derived from a single progenitor cell in which a molecular event took place that gave rise to attenuated G_2 arrest. The molecular mechanism underlying attenuation remains to be determined. Attenuation in patients with FA contributes to the variability in disease expression and identifies patients with a milder presentation of BMF but who might need continuous, intensified tumor surveillance.

Mouse Models for Fanconi Anemia

Orthologues of FANCD2, FANCM, and FANCL are found in nonvertebrates, whereas the other members of the FA core complex have evolved in vertebrates. To study clinical phenotypes and develop possible new therapeutic strategies, several mouse models for FA have been generated by introducing mutations into murine *Fanc* genes, including *Fanca*, *Fancc*, *Fancg*, *Fancd2*, *Fancd1*, *Fancf*, *Fancl*, *Fancm*, *Fancn*, *Fanco, and Fancp*.[129] Homozygous null mutations were lethal for *Fancd1*, *Fancn, Fanco,* and some *Fancl* embryonic mice, depending on the genetic background; this finding confirms what had already been suspected from the mutation analysis in patients with FA, namely that some residual function in these *FANC* genes is required for a living organism. Some models recapitulate the clinical features seen in patients with FA, specifically microphthalmos, germ cell defects, chromosomal instability, and increased sensitivity to cross-linking agents. In some models tumors develop with increased frequency, and tumor formation is more pronounced in the absence of p53. These models underline the importance of the FA pathway in tumorigenesis. Hematopoietic progenitor cells from mice homozygous for a null mutation in the *Fancc* gene demonstrate a distinct hypersensitivity to IFN-gamma that leads to cell death independent of the DNA repair pathway mediated by FAS-induced apoptosis, suggesting that IFN-gamma hypersensitivity may play a major role in the pathogenesis of BMF in patients with FA. Interestingly, however, although *Fancd1*- and *Fancp*-deficient mice have a reduced number of HSCs and decreased white blood cell and platelet counts, spontaneous development of aplastic anemia was not observed in these mice. Mice deficient in *Fancd1* are exquisitely sensitive to excess acetaldehydes from endogenous and exogenous sources.[71] Aldehydes are produced endogenously during normal metabolism or as a by-product of ethanol metabolism and can induce DNA-DNA and DNA-protein cross-links. Aldehydes are detoxified by aldehyde dehydrogenases. Interestingly, hematopoietic stem cells in mice express the aldehyde dehydrogenase *Aldh2*, which is essential for protection against acetaldehyde toxicity, suggesting that the FA pathway is needed to protect from aldehyde-mediated genotoxicity.[89] Although these findings need to be confirmed in humans, they would explain why hematopoiesis is preferentially affected in FA but is not affected, or not to the same extent, in other non-FA DNA repair disorders.

Induced Pluripotent Stem Cells Derived from Patients with Fanconi Anemia

Induced pluripotent stem cells (iPSCs) are derived from human somatic cells through ectopic expression of transcription factors.[130] Since their discovery these cells have become a widely used tool for modeling and studying IBMFSs.[131] Their unlimited self-renewal capacity, pluripotency, and ease of accessibility are very promising for disease modeling, cell-based therapy, and drug discovery. Interestingly, the generation of iPSCs from FA patients is challenging due to a low reprogramming efficiency in the presence of a defective FA pathway,[132] suggesting that cellular reprogramming or the methodology (integrating viruses) of reprogramming requires an intact FA pathway. FA iPSC lines are capable of undergoing hematopoietic differentiation, but the hematopoietic progenitors undergo increased apoptosis and have a reduced clonogenic potential.[133,134] Further investigation using the iPSC FA disease model is likely to provide exciting insights into the disease pathology and future treatment options.

Clinical Management

Once the diagnosis is confirmed, the family should be referred to a clinical geneticist for counseling and careful examination of family members. Genetic testing or chromosome breakage analysis should be offered to all family members. Early diagnosis is important for correct management of hematologic complications, diagnosis and appropriate treatment of coexisting congenital abnormalities and associated endocrinopathies, and identification of affected but asymptomatic family members and unaffected family members or pregnancies that may serve as potential hematopoietic stem cell donors. In addition, early diagnosis allows targeted cancer surveillance, not only in patients with FA but also in some cases in heterozygous mutation carriers (also see earlier). Management of patients in whom FA is diagnosed depends on the age at diagnosis and the presence or absence of congenital or hematologic abnormalities (see also Fanconi Anemia: Guidelines for Diagnosis and Management, Third Edition, 2008; available from the Fanconi Anemia Research Fund at fanconi.org/). All diagnosed FA patients should have a full hematologic assessment, including examination of bone marrow, and HLA typing should be performed in anticipation of possible HSCT. Other investigations at diagnosis should include audiometry, ophthalmic examination, renal ultrasound studies, and endocrine assessment. Referral to specialized surgeons might be necessary for correction of radial ray defects.

Management of Hematologic Disease

Initially, in the absence of hematologic abnormalities or clinical and laboratory signs of mild BMF, monitoring of peripheral blood values and yearly examination of bone marrow might be sufficient. Bone marrow examination should include a trephine biopsy and marrow aspirate for examination of marrow cellularity and morphologic changes characteristic of MDS, as well as for cytogenetic examination by G banding and fluorescent in situ hybridization (FISH) analysis, including probes that identify the most frequent cytogenetic abnormalities seen in patients with FA and progression to MDS or AML (see the section on Myelodysplastic Syndrome and Acute Leukemia in Patients with Fanconi Anemia).[44] Plans for possible HSCT should be in place because hematologic complications may develop rapidly. With progression of BMF it will become necessary to increase the frequency of hematologic monitoring. HSCT is usually considered in patients with moderate BMF and an available HLA-matched unaffected sibling donor or when BMF becomes severe and an unrelated donor is available. Preventive HSCT in the absence of hematologic disease is highly controversial and currently considered investigational because the risk and time course of disease progression are highly variable and have to be weighed against the morbidity and mortality associated with HSCT. However preventive HSCT might be considered in patients with biallelic *BRCA2* mutations associated with a higher risk of leukemic transformation.

Management of FA patients with MDS or AML, or both, is less standardized. The significance of transient clonal cytogenetic abnormalities limited to a single chromosome is unclear, but if they are persistent or complex, such abnormalities may predict a poor prognosis; the exception is an isolated trisomy 1q that might be present years before the development of MDS (see the section on Myelodysplastic Syndrome and Acute Leukemia in Patients with Fanconi Anemia).[44] HSCT with or without induction chemotherapy or enrollment in clinical trials for MDS or MDS/AML is usually considered.[135] Androgens such as oxymetholone, methyl testosterone, or danazol and hematopoietic growth factors transiently improve BMF in 50% to 60% of FA patients.[136,137] Side effects of androgen therapy include masculinization, acne, hyperactivity, growth spurt followed by premature closure of the epiphyseal growth plates, high serum lipid levels, liver enzyme abnormalities, hepatic adenomas (with danazol), and a risk for hepatic adenocarcinomas (with androgens) that requires frequent monitoring of liver function and liver ultrasound scanning.[40,138] The effect of pretransplantation androgen use is controversial. Hematopoietic growth factors [granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF)] may transiently improve neutrophil counts and, in rare FA patients, hemoglobin levels and platelet numbers. The use of hematopoietic growth factors in patients with clonal cytogenetic abnormalities is controversial because of the potential risk of inducing or promoting leukemia. Anti-inflammatory agents such as anti-TNF-alpha and antioxidants have been shown to improve hematopoiesis in vitro and in mouse models and are currently being tested in clinical trials for efficacy and safety in patients with FA.[139,140] Red cell transfusion therapy and iron chelation (after multiple red cell transfusions) are frequently used in symptomatic FA patients. Platelet transfusions may be indicated in thrombocytopenic patients with bleeding or before surgical procedures.

HSCT from an HLA-matched sibling donor is accepted as the best treatment to cure BMF in FA patients and to prevent progression to MDS and AML. Early experiences with HSCT for the treatment of BMF were disastrous because of excessive regimen-related toxicity. Early conditioning regimens consisted of cyclophosphamide alone or in combination with total-body irradiation (TBI). Unfortunately, severe toxicities (e.g., gastrointestinal hemorrhage, hemorrhagic cystitis, cardiomyopathy, and skin burns) were common. Gluckman and colleagues[141] proposed the use of a less intensive conditioning regimen consisting of low-dose cyclophosphamide and thoracoabdominal irradiation for patients with FA. This approach proved to be a major advance in the treatment of patients who had HLA-matched sibling donors.[118,142] However, it did not afford consistent engraftment in recipients of unrelated donor transplants, with graft rejection rates exceeding 20%,[143] and head and neck cancer was frequent after HSCT.[144] Consequently, HSCT without irradiation is increasingly used for patients with FA and a matched sibling donor using fludarabine and cyclophosphamide and with T cell depletion either of the graft or in vivo with rabbit ATG or alemtuzumab to prevent graft-versus-host disease (GVHD).[145] Recent studies suggest that fludarabine-based conditioning regimens are associated with improved survival rates in patients undergoing related or unrelated donor HSCT and have significantly improved survival rates for alternative donor transplant recipients.[146-148] The use of irradiation for alternative donor transplant varies among countries and transplant centers.[149-151] Transplant-related mortality and GVHD remain a problem. Furthermore chronic GVHD significantly increases the risk of squamous cell carcinoma in FA patients who undergo HSCT.

PGD may be used in parents with a previously affected child to select embryos that are both unaffected by FA (if a *FANC* gene mutation is known) and have HLA matched to the affected sibling. HSCT is performed with the HLA-matched umbilical cord blood of the unaffected newborn.[152,153]

Unrelated cord blood as an alternative HSC source showed an overall survival rate of 53% with fludarabine in the conditioning regimen (vs. a rate of 19% without fludarabine). There was a relatively high incidence of GVHD and transplant-related mortality rates of 32% and 59%, respectively, suggesting that unrelated cord blood transplant should be considered only when other alternative donor stem cell sources cannot be found. Alternatively a mismatched or haploidentical family donor may be a valid option if no matched unrelated donor can be found.[154]

Cancer Surveillance and Treatment

For FA patients who survive the hematologic complications, follow-up surveillance for solid malignant tumors becomes increasingly important. There are no clear guidelines on the treatment of cancer in FA patients, which is complicated because the increased sensitivity to irradiation and certain chemotherapeutic agents may result in enhanced toxicity and an increased risk of therapy-induced secondary malignant diseases.

Gene Therapy

HSCT may cure hematologic disease in FA patients; however, HLA-matched sibling donor cells are available only for a minority of patients. Gene therapy to correct HSCs, followed by autologous transplantation, offers an attractive alternative for the treatment of hematologic disease. Indeed, gene transfer corrects the hypersensitivity of most FA cell lines to DNA cross-linking agents in vitro (with the exception of FANCM, most likely because of the insolubility of the protein) and the hypersensitivity of FA knockout mice in vivo. The high incidence of somatic mosaicism and the often ameliorated course of hematologic disease in these patients (frequently referred to as the *gene therapy of nature*) suggest that FA cells corrected by gene therapy are likely to have a selective growth and survival advantage. However, gene therapy attempts in FA patients have thus far been rather disappointing,[155,156] mainly because of the lack of permanent gene correction and the difficulty in culturing FA bone marrow cells in vitro. Multiple investigations are currently addressing the major difficulties of gene therapy for FA, including the scarcity of hematopoietic stem cells in patients with BMF, the extraordinary fragility of FA hematopoietic progenitor cells, and the increased sensitivity of FA hematopoietic progenitor cells to oxidative stress, which makes it difficult to culture and transduce FA hematopoietic progenitor cells in vitro. There is also a risk that the transduced hematopoietic cells might already have acquired secondary somatic, and possibly oncogenic, mutations and that correction by gene therapy would promote rather than prevent leukemogenesis. The International FA Gene Therapy Working Group was formed to accelerate the transition from research to clinical gene therapy trials and coordinating activities on an international scale.[157]

Dyskeratosis Congenita

Dyskeratosis congenita (DC), also known as *Zinsser-Cole-Engman syndrome*, is genetically and phenotypically heterogeneous (Box 7-8). It was first described by Zinsser and recognized as a clinical entity by Cole and Engman.[158-160] DC was originally perceived to be a dermatologic disorder affecting the skin, nails, and mouth. Its association with BMF and squamous cell cancer arising from the skin or from leukoplakia in the mouth or anus was recognized later.[161]

Box 7-8 Dyskeratosis Congenita[162,163]

Dyskeratosis congenita is a rare inherited bone marrow failure syndrome with an X-linked, autosomal dominant, and autosomal recessive inheritance. However, more than half of patients present with sporadic disease. Classically, bone marrow failure in these dyskeratosis congenita patients is associated with the mucocutaneous triad including abnormal pigmentation, dystrophic nails, and mucosal leukoplakia. Patients with dyskeratosis congenita have a defect in telomere maintenance, and at the time of bone marrow failure peripheral leukocytes have very short telomeres (see Fig. 7-9).[162,163]

Clinical Manifestations

Originally, DC was clinically recognized by the classic diagnostic triad of reticular pigmentation of the skin, nail dystrophy, and mucosal leukoplakia (Figure 7-7).[158-160] Other signs and symptoms found frequently in classic DC are summarized in Table 7-6.[164,165] The classic clinical course is mucocutaneous features first appearing in childhood, BMF developing in adolescence, and death occurring in young adulthood. Cytopenias due to BMF, immune deficiency, pulmonary fibrosis, and malignant disease are the major causes of death.

The identification of nine of the genes responsible for DC and the realization that these genes converge into a common pathway have changed the perception of this disease. It is now thought that individuals in whom DC is diagnosed on the basis of BMF and the classic cutaneous manifestations represent only a fraction of those who suffer from this condition.[166,167] Whether affected individuals in the absence of cutaneous disease should be labeled with the diagnosis of "dyskeratosis congenita" or whether the disease should be renamed with a term better reflecting the pathogenetic pathway is still under debate. Here we will use the conventional nomenclature and clinically classify patients as having classic, atypical, or silent DC. Patients who have two or more of the three diagnostic mucocutaneous features or who have one of the mucocutaneous features and hypocellular bone marrow with all three blood cell lineages affected are those with classic DC. Patients with BMF but lacking mucocutaneous features or patients with clinical manifestations of DC other than hematologic disease or

TABLE 7-6 Prevalence of Clinical Features in Patients with Classic Dyskeratosis Congenita

Characteristic	Alter 2003[27] (%)	Vullamy & Dokal 2006[724] (%)
Diagnostic mucocutaneous features		
Skin pigmentation	88	89
Nail dystrophy	73	88
Leukoplakia	64	78
Eye abnormalities/epiphora	38	31
Teeth abnormalities/caries/loss	19	17
Learning difficulties/ developmental delay/cognitive disability	14	25
Pulmonary diease/fibrosis	20	
Skeletal anomalies	14	
osteoporosis/avascular necrosis/scoliosis		5
Short stature	14	20
Hyperhidrosis	10	15
Hair loss, early graying	18	16
Urinary tract abnormalities	7	
Urethral stricture/phimosis		5
Gastrointestinal abnormalities	14	
Liver fibrosis/ulcer/enteropathy	7	
Esophageal stricture		17
Other conditions	11	
Gonadal anomalies/ hypogonadism/undescended testes	5	6
Intrauterine growth retardation		
Ataxia/cerebellar hypoplasia	7	
Microencephaly	8	
Malignant disease	12	10

mucocutaneous features, such as pulmonary fibrosis, are those with atypical DC. Individuals with no clinical manifestations but carrying a pathogenic mutation are classified as having silent DC. Our knowledge about the natural history of DC is biased because early studies focused on patients with the classic clinical manifestations. Our experience is still limited about the course of disease, response to treatment, and late complications in individuals with atypical or silent DC.

Classic Dyskeratosis Congenita

Mucocutaneous Features. Mucocutaneous abnormalities are the hallmark of classic DC (see Fig. 7-7).[168] The most commonly observed mucocutaneous abnormality (>90%) is reticulated skin hyperpigmentation on the neck, face, chest, and arms. It may be extensive or localized and tends to increase with age. Other cutaneous manifestations include alopecia, sparse hair, premature hair graying, hyperhidrosis, hyperkeratosis of the palms and soles, and loss of dermal ridges on the fingers and toes.

Nail dystrophy is another frequent finding (>80%). Progressive nail dystrophy starts with ridging and longitudinal splitting and may proceed via atrophy and thinning to complete nail loss. The severity of nail dystrophy may vary among the digits; fingernails are usually more severely affected than toenails.[169]

Mucosal leukoplakia occurs in the majority of patients (>70%) and typically involves the tongue, buccal mucosa, and oropharynx, with the tongue being the most frequently affected site.[170] Mucosal leukoplakia may be the initial clinical manifestation of disease. Consequently, dentists or oral surgeons may be the first health professionals consulted. Histologic examination reveals hyperkeratosis or a lichenoid reaction. Other sites of leukoplakia include the urethra, glans penis, vagina, and anorectal region.[168] DC patients have an increased risk of malignant disease arising from the preexisting leukoplakia; the incidence of malignant transformation has been estimated to be 35%.[171]

Hematologic Abnormalities. About 85% of patients with classic DC are initially found to have cytopenia of one or more lineages, and pancytopenia develops in more than 95% by 40 years of age.[164] The overall cumulative incidence of BMF in all patients with DC (typical and atypical) is approximately 50%.[41] Often the degree of aplasia in the bone marrow is striking despite only a moderate degree of peripheral blood cytopenia. Complications of BMF, such as hemorrhage or opportunistic infection, represent the major causes of death in patients with DC. In patients with atypical DC, BMF may appear before the classic mucocutaneous features and lead to an initial diagnosis of idiopathic aplastic anemia. Hypoplastic MDS and MDS/AML are increasingly diagnosed in patients with DC, especially in those with a milder course or an atypical form of the disease. Indeed, MDS or MDS/AML may be the initial manifestation of patients with atypical DC.

Combined immune deficiency is frequently associated with DC, particularly in children with severe and early onset of disease. Reduced or absent B cells and reduced NK cells are frequent; other findings in young patients include decreased T-cell numbers, low immunoglobulin levels, and a lack of lymphocyte proliferation in response to antigens.[172,173]

Other Clinical Features. Pulmonary complications are common (>20%) and include pulmonary fibrosis and vascular abnormalities.[174,175] Pulmonary fibrosis is usually a more prominent finding in older patients or after BMT.[176] In some patients with atypical DC, pulmonary fibrosis may be the only clinical manifestation. Figure 7-8 shows a family with autosomal dominant DC and pulmonary fibrosis. Families with hereditary pulmonary fibrosis of adult onset should be investigated for DC, particularly when pulmonary fibrosis is associated with macrocytic anemia or other cytopenias.[177,178] In families with pulmonary fibrosis and BMF, a pathogenic DC gene mutation is almost always responsible for both conditions; in such kindreds pulmonary disease typically manifests in the sixth decade of life,

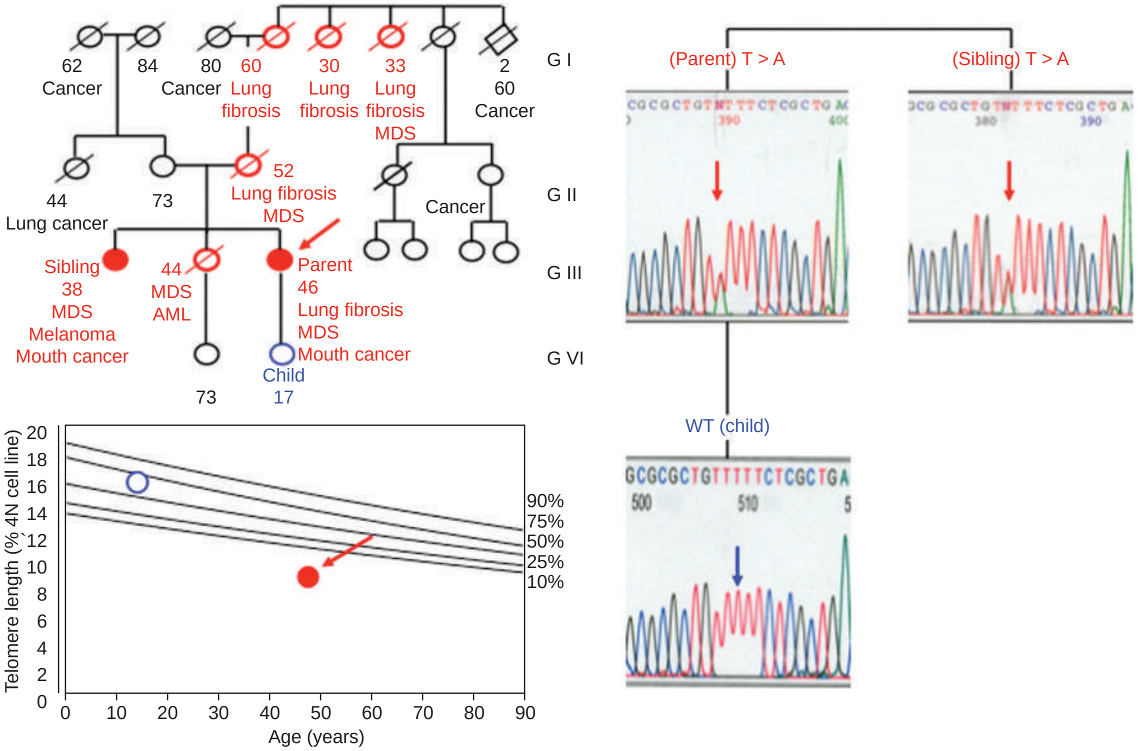

Figure 7-8 **A**, Pedigree of a family with dyskeratosis congenita due to a *TERC* gene mutation. Note, in addition to myelodysplastic syndrome, pulmonary fibrosis is a prominent feature of dyskeratosis in this family (to protect privacy, gender identification has been removed). **B**, Chromatogram demonstrating that the parent and the sibling are heterozygous for the *TERC* gene mutation, whereas the child has not inherited the mutation. **C**, Telomere length of the affected parent (below and outside of telomere length distribution of normal controls) and the nonaffected child (normal telomere length). Lines indicate the 10th, 25th, 50th 75th, and 90th percentile of telomere length determined in 105 healthy controls between the ages of 1 and 95 years.

whereas BMF manifests in the first or second decade (see Fig. 7-8).[179]

Liver fibrosis may be a late manifestation of DC. As with pulmonary fibrosis, liver fibrosis tends to occur in older patients or after BMT. In some patients liver fibrosis might be the only or first manifestation of disease. Excessive alcohol consumption or acute hepatitis is thought to accelerate liver fibrosis and severity in patients with a pathogenic DC mutation.[180-182] The presence of a DC mutation does not preclude the development of hepatocellular carcinoma.[182]

Ocular findings include epiphora (excessive tearing caused by blocked lacrimal ducts), blepharitis, cataracts, loss of eyelashes, conjunctivitis, ectropion, glaucoma, strabismus, ulcers, ocular albinism, and exudative retinopathy (*Coats retinopathy*).[183-186] Interestingly, Coats retinopathy is specific for *Revesz syndrome* (caused by mutations in *TINF2*) and *Coats- plus syndrome* (caused by mutations in *CTC1*); exudative retinopathy is not typical of other forms of DC. Corneal limbal insufficiency owing to impaired corneal stem cell function has also been described in patients with DC.[187]

Sparse hair and early graying are common. Dilated cardiomyopathy due to cardiac fibrosis has been associated with DC.[188]

Multiple dental caries early loss of teeth, and a bifid uvula are common oral manifestations of DC.[189,190] Gastrointestinal abnormalities include web formation in the upper esophagus, esophageal stricture, severe necrotizing ulcerative pancolitis in infants, and chronic diarrhea with malabsorption due to mucosal villous blunting in young adults.[191-194] Patients have an increased risk of esophageal, rectal, and possibly gastric cancers.[41]

Genitourinary abnormalities include hypospadias, phimosis, and urethral strictures. Underdeveloped testes and azoospermia have been reported in more severe and advanced forms of DC.

Cognitive deficiencies such as learning disorders are common in classic DC. In rare cases an association with schizophrenia has been described. Other neurologic manifestations may include cerebellar ataxia due to cerebellar hypoplasia, intracranial calcification, and hypoplasia of the corpus callosum, pituitary gland, or brainstem.

Osteoporosis and avascular necrosis of the bones, in particular the hips, is frequent and probably underappreciated and may complicate the course of the disease. In some forms of DC avascular necrosis of the bones occurs at a very young age and may be the dominating clinical feature. Short stature and an elf-like appearance have been associated with classic DC.[195]

Predisposition to Malignant Disease

DC is a syndrome that predisposes to cancer.[161,162,164] After BMF and pulmonary complications, malignant disease is the third leading cause of death. The cumulative incidence has been estimated to be 20% to 30% by the age of 50 years.[41] The most frequent malignant tumors in patients with DC are squamous cell carcinoma of the head and neck (especially the tongue but also the lip, mouth, palate, cheek, nasopharynx, and larynx),[170,171,190] the upper and lower gastrointestinal tract (esophagus and anus), and the female genital tract. Other reported malignant tumors include skin cancer and adenocarcinoma of the stomach, colon, lung, and pancreas.[41] Whether all forms of DC have equal risks of predisposition to cancer remains to be determined. Malignant tumors usually develop in the third decade and are therefore more frequently found in individuals with milder and late-onset forms of the disease (see Table 7-1).

MDS and MDS/AML are common in patients with atypical DC and in patients with late-onset of the disease (see Fig. 7-7, *E*). The cumulative incidence of MDS has been estimated to be about 30% and that of MDS/AML approximately 10% by the age of 50 years.[41] MDS or MDS/AML may be the first hematologic manifestation of disease. Although DC is rarely a cause of MDS or MDS/AML in children,[196] it should be considered in the differential diagnosis in young adults with MDS or MDS/AML. Abnormalities of chromosome 7 (monosomy, isochromosome, or other structural rearrangements) are the most common cytogenetic abnormalities in patients with DC-associated MDS or MDS/AML.

Little is known about the biology of leukemia or other cancers in patients with DC and to what extent these malignant diseases differ from those seen in patients without DC. The cancer recurrence rate is high in patients with DC.

Laboratory Findings

Common laboratory findings are summarized in Box 7-9. In most patients, the initial hematologic abnormalities are thrombocytopenia or macrocytic anemia followed by pancytopenia. Bone marrow examination often reveals increased cellularity at the outset, suggesting an element of hypersplenism. However, hypocellularity then ensues, consistent with the diagnosis of aplastic anemia. Macrocytosis and elevated hemoglobin F levels *(stress erythropoiesis)* are common.[197] The number of circulating hematopoietic progenitor cells is decreased, indicative of the impairment in hematopoiesis at the stem cell level.

Bone marrow examination usually shows hypocellular marrow affecting all three blood cell lineages. The hypocellularity of the bone marrow is often striking in comparison with rather moderate cytopenias in the peripheral blood. Hypocellular MDS or MDS/AML is increasingly being found in patients with atypical DC or a late onset of disease. Monosomy 7 is the most frequent clonal cytogenetic abnormality in patients with MDS or MDS/AML.

Long-term culture assays of bone marrow cells show a decreased number of progenitor cells and an impaired capability for colony formation, indicative of a quantitative and qualitative defect.[198]

Immunologic abnormalities may include humoral and cellular defects (summarized in Box 7-9).[172,173,199] Severe combined immunodeficiency is characteristic of severe forms of DC.

Box 7-9 Laboratory Findings in Patients with Dyskeratosis Congenita*

1. **Peripheral blood findings**
   - Cytopenia of one or more lineages (80%):
   - Initial presentation highly variable:
     - macrocytosis +/– anemia
   - Thrombocytopenia
   - Neutropenia
   - Pancytopenia
   - Low number of circulating progenitor cells
   - Elevated hemoglobin F
   - Elevated von Willebrand factor
2. **Bone marrow examination**
   - Hypocellular bone marrow affecting all three lineages
     - Increased number of mast cells
     - Dyserythropoiesis
   - Hypocellular myelodysplastic syndrome
   - Myelodysplastic syndrome/acute myeloid leukemia
3. **Immunologic findings**[172,173]
   - Humoral abnormalities:
     - Hypogammaglobulinemia or hypergammaglobulinemia
   - Cellular abnormalities:
     - Lymphopenia: B cells, T cells, NK cells
   - Functional abnormalities:
     - Proliferation upon stimulation is reduced
     - Increased apoptosis upon stimulation
     - Anergy
     - Difficulty in immortalization by Epstein-Barr virus transformation
4. **Cellular abnormalities**
   - Premature replicative senescence[201,208]
   - No increased chromosomal breakage after cross-linking agents
   - Hypersensitivity to ionizing irradiation (controversial)
   - Increased sensitivity to certain cytotoxic agents
   - Difficulty in immortalization by TERT[208]
   - Difficulty in reprogramming to induce pluripotent stem cells[210]
5. **Cytogenetic abnormalities**[200-202]
   - Chromosomal instability: Nonclonal complex anomalies in cultured cells:
     - Chromosomal breaks, hypodiploidy, micronuclei,
     - anaphase and telophase bridges,
     - short telomeres/signal free ends[725]
     - end-to-end fusion with no telomeric signal
   - No increase in chromsomal instability after clastogenic effects of
     - DNA
     - cross-linking agents
   - Biased X-inactivation (female carrier of X-linked dyskeratosis congenita)[204,205]
   - Clonal abnormalities in bone marrow cells : monosomy 7 (myelodysplastic syndrome, myelodysplastic syndrome/acute lymphocytic leukemia)

*Laboratory findings in bold are characteristic for dyskeratosis congenita.

DC cells have increased spontaneous chromosomal instability that leads to distinctive chromosomal breaks, rearrangements,[200,201] and sister chromatid exchanges.[202,203] Chromosomal instability increases as DC cells are passaged in vitro. Chromosome breakage does not increase after treatment with alkylating agents such as DEB, MMC, or nitrogen mustard,[202] a finding that distinguishes DC from FA. Chromosomal abnormalities characteristic of DC include end-to-end fusions, dicentric or tricentric chromosomes, anaphase or telophase bridges, short telomeres, and telomere free ends.

Paternally or maternally biased X-inactivation in blood cells, as well as in fibroblasts from buccal mucosa

Box 7-10 **Measurement of Telomeres, Telomerase, and Telomere Length**

Telomeres are complex DNA/protein structures at the ends of chromosomes that are needed to protect chromosome ends from degradation and distinguish them from double-stranded breaks.[233] Human telomere DNA consists of thousands of repeats of TTAGGG (see Fig. 7-10, *A* and *B*). Most somatic cells lack telomerase, so telomeres shorten with each cell division[234] owing to the inability of DNA polymerase I to copy the extreme end of a DNA strand.[235] In most tissues, therefore, telomere length decreases with age.[236] When telomeres become critically short, cell cycle arrest or cell death occurs (see Fig. 7-11).[237] In germ cells,[238] some stem cells,[239,240] and most cancer cells,[237,241] telomeres are maintained by the action of the enzyme *telomerase*,[242] which contains two core components, a reverse transcriptase TERT (telomerase reverse transcriptase) and an RNA molecule, *TERC* (telomerase RNA component), which acts as a template for the synthesis of telomere repeats (see Fig. 7-10, *C* and *D*).

and skin biopsy samples in female mutation carriers, is characteristic of X-linked DC.[204,205]

The presence of short telomeres in circulating peripheral blood cells is a hallmark of patients with BMF and DC.[162,163] Telomere length in individuals with BMF secondary to DC is far below the normal distribution of telomere length in age-matched healthy control individuals (Box 7-10 and Fig. 7-9).[162,163] In contrast to other IBMFSs, which may have short telomeres in circulating myeloid cells, telomeres are exquisitely short in the myeloid and lymphoid cells of patients with DC-associated BMF.[163] Telomere length measurements of circulating peripheral blood lymphocytes (or total blood cells, although less sensitive) are therefore used to screen patients with BMF for DC; normal telomere length makes DC an unlikely cause of BMF.[163] Similarly, very short telomeres in circulating lymphocytes are highly suggestive of DC, but the diagnosis should be reserved for patients with classic clinical DC features or an identified pathogenic DC mutation.[163]

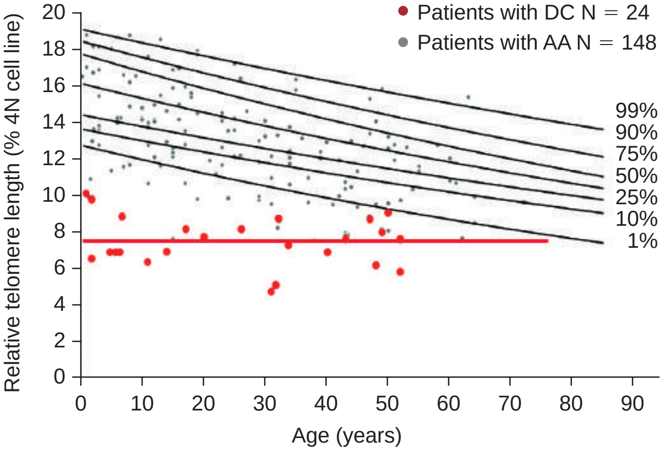

Figure 7-9 Telomere length in peripheral blood mononuclear cells in individuals with dyskeratosis congenita and bone marrow failure. In all individuals with dyskeratosis congenita and bone marrow failure, telomere lengths are below and outside of telomere length distribution of normal controls. The black lines indicate the 1st, 10th, 25th, 50th 75th, 90th, and 99th% percentile of telomere length determined in 148 healthy controls between the ages of 1 and 95 years. The gray dots indicate telomere length in 148 patients with aplastic anemia due to other causes than dyskeratosis congenita. *(Modified from Du HY, Pumbo E, Ivanovich J, et al: TERC and TERT gene mutations in patients with bone marrow failure and the significance of telomere length measurements.* Blood *113:309–316, 2009.)*

Cellular Phenotype of Dyskeratosis Congenita Cells

In addition to increased spontaneous chromosomal instability, DC cells exhibit several other phenotypic characteristics, as summarized in Box 7-9. DC cells have been reported to have increased sensitivity to ionizing radiation and certain chemotherapeutic agents (e.g., bleomycin), although these findings were not consistent among all investigators.[202,206,207] Decreased proliferation capacity in vitro and premature replicative senescence are also characteristic of DC cells (see Box 7-9).[201,208] Cells from classic and more severe forms of DC (X-linked DC) fail to immortalize after Epstein-Barr virus–induced transformation or after transfection of a plasmid expressing the telomerase catalytic subunit TERT.[208] Similarly the reprogramming of DC skin cells into iPS cells is difficult,[209,210] and reprogrammed iPS cells are not immortal.[210]

Differential Diagnosis

Clinically, BMF in patients with DC has to be distinguished from other forms of BMF, including acquired aplastic anemia, familial aplastic anemia, and IBMFSs such as FA (MIM 227650), Seckel syndrome (MIM 606593), DNA ligase IV deficiency (MIM 606593), and Shwachman-Diamond syndrome (SDS, MIM 260400). Reticulate hyperpigmented disorders including Naegeli-Franceschetti-Jadassohn syndrome (MIM 161000), dermatopathia pigmentosa reticularis (MIM 125595), X-linked reticulate pigmentary disorder, incontinentia pigmenti (MIM 308300), and poikiloderma with neutropenia (MIM 604173) need to be distinguished from DC. Clinical manifestations, associated physical abnormalities, the family history (pattern of inheritance), and the lack of increased chromosomal fragility in the DEB or MMC test performed on cultured peripheral lymphocytes or fibroblasts (or both) are helpful in strengthening the diagnosis of DC. As noted earlier, telomere length below the normal distribution strongly suggests DC, whereas normal telomere length makes DC an unlikely cause for BMF in these patients.[163] X-inactivation studies may be helpful in identifying female carriers of the X-linked form of DC.[205]

Genetic Characteristics

Inheritance. There are four distinct forms of inheritance of DC. Historically, before molecular diagnostic testing was available, inheritance was determined by examining family members for the presence of clinical manifestations. Today, we know that such classification was often mistaken because of the variability of penetrance of gene mutations.

X-linked Dyskeratosis Congenita. The most common form of classic DC is the X-linked form (MIM 30500), and many families with classic DC and X-linked inheritance have been described. The X-linked form is almost always due to single point mutations in the *DKC1* gene encoding dyskerin.

Autosomal Dominant Dyskeratosis Congenita. Several families have been described with an autosomal dominant (AD) form of inheritance of DC (AD DC, MIM 127550). This form exhibits genetic anticipation (Box 7-11). Several pedigrees in which AD DC is caused by mutations in the *TERC* gene encoding telomerase RNA have been described. In addition, families in whom AD DC appears to be due to mutations in *TERT*, which encodes the telomerase reverse transcriptase, have been reported. Mutations in the shelterin component TIN2, encoded by *TINF2*, are dominant in that a severe form of DC is caused by heterozygous mutations. However, these patients seldom have children, and the disease is sporadic, caused by de novo mutations.[211,212]

Autosomal Recessive Dyskeratosis Congenita. A number of families have been described with autosomal recessive (AR) DC (MIM 224230). AR DC is usually inferred when neither parent has any signs of DC but two or more children have the disease or when the parents of an affected child are consanguineous. Some families originally thought to have AR DC were found to have AD DC with variable penetrance and expressivity, mimicking sporadic or AR disease.[213-215] Rare cases of AR DC are due to biallelic mutations in *TERT, TERC, NOP10, NHP2*, and *WRAP53*. More commonly, recessive forms of DC are due to mutations in *CTC1* and *RTEL1*.

Sporadic Dyskeratosis Congenita. A large proportion of DC cases arise sporadically (i.e., neither parent of an affected child has the disease). Of 123 such male cases from the DC registry in the United Kingdom, 40 were found to have a de novo *DKC1* mutation and 3 were found to have an inherited *TERC* mutation with variable penetrance and expressivity in the affected family. Eighty had neither *TERC* nor *DKC1* mutations. Similarly, all 35 female cases had neither *TERC* nor *DKC1* mutations. These sporadic cases account for more than half of DC patients.[215,216] Most cases due to *TINF2* mutations are sporadic, due to the fact that most patients with this severe form of DC do not reproduce.[211]

Dyskeratosis Congenita Genes and Their Functions

DKC1 and Dyskerin. X-linked DC is caused by mutations in the *DKC1* gene at Xq28. *DKC1* was identified by positional cloning in families with affected males and biased X-inactivation in female carriers.[217] The *DKC1*-encoded protein dyskerin is a 58-kD nucleolar protein orthologous to proteins in yeast, flies, and rats (Cbf5p,[218] Nop60B/minifly,[219] and NAP57,[220] respectively).

Dyskerin is associated with box H/ACA RNA molecules in ribonucleoprotein (RNP) complexes. Box H/ACA RNP complexes consist of four different proteins (dyskerin, GAR1, NOP10, and NHP2) and an integral RNA species.[221] The box H/ACA RNA determines the function of the RNP complex. The majority of box H/ACA RNAs are small nucleolar RNAs (snoRNAs) found in the nucleolus. These snoRNAs guide the protein complex containing dyskerin by complementary base pairing to specific uridine residues of newly synthesized ribosomal RNA (rRNA) molecules, which are then modified by pseudouridylation. In snoRNP dyskerin is the enzyme, a pseudouridine synthase, that actually catalyzes the pseudouridylation reaction.[222,223] The role of pseudouridylation is not known, but pseudouridines tend to be found in the conserved sequences of rRNA and transfer RNA (tRNA) in regions of high secondary structure, and it is likely that these modifications stabilize the secondary and tertiary structures of RNA molecules. Other box H/ACA RNAs that associate with dyskerin and the three other proteins of the complex participate in ribosome biogenesis downstream of rRNA modification or messenger RNA (mRNA) splicing or are orphan RNAs, the function of which remains to be determined.[221]

Telomerase RNA (*TERC*, telomerase RNA component), which along with TERT (telomerase reverse transcriptase) forms the core of the telomerase enzyme, also associates with dyskerin and the other three proteins present in H/ACA-class snoRNP (Fig. 7-10, *C*).[224,225] The conserved secondary structure of the 3′ end of telomerase RNA is very similar to that of H/ACA RNAs. This part of the telomerase RNA and its association with H/ACA RNP components are found only in vertebrates, whereas the H/ACA RNP components themselves are highly conserved among all eukaryotes. The four proteins may be involved in transport, stability, and assembly of the telomerase complex in the nucleolus. There is no evidence that the H/ACA part of telomerase RNA functions as a guide RNA or that dyskerin exhibits any pseudouridylation activity as part of the telomerase complex.

The diverse function of dyskerin in humans raises the interesting question of whether and to what extent the pathogenesis of X-linked DC is caused by defects in telomerase activity or in other functions of RNP, such as rRNA metabolism.

NOP10. Autozygous mutations (homozygous mutations in a consanguineous family) in the *NOP10* gene on chromosome 15q14 have been found to be responsible for disease in a single family.[226] NOP10, like dyskerin, is an essential component of H/ACA RNP complexes and thus participates in the same pathways as dyskerin (see Fig. 7-10, *C*).[225,227]

NHP2. Two families have been described with biallelic mutations in *NHP2*. NHP2, like dyskerin and NOP10, is an essential component of H/ACA snoRNP complexes (see Fig. 7-10, *C*).[225,227]

TERC, TERT, and Telomerase. AD DC is caused by mutations in the *TERC* gene, also abbreviated as *hTR or TER*, which is found on chromosome 3q26.[228] *TERC* was identified as the gene responsible for AD DC through positional cloning. It encodes the RNA component of the telomerase complex. Telomerase, the enzyme responsible for elongating and maintaining telomeres, synthesizes telomeric DNA repeats by using *TERC* RNA as a template (see Box 7-10 and Fig. 7-10, *C and D*). Nonsynonymous mutations have also been identified in the *TERT* gene localized on 5p15.33.[229-231] TERT is the catalytic part of the telomerase complex (see Box 7-10 and Fig. 7-10, *C*). *TERT* was identified as a gene responsible for

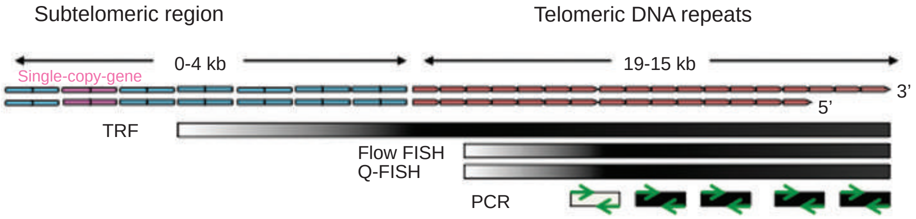
Figure 7-10 **A**, Telomeres and telomere structure. Telomeres are complex DNA protein structures that protect the ends of chromosomes in every cell. The organization of DNA ends at telomeres is highly conserved. Telomeric DNA is composed of short, direct repeats. **B**, In quiescent cells the telomeres adopt a looplike structure, the T loop, which hides the end of chromosomes from degradation and end-to-end fusion (see also Box 7-10).[101] **C**, A number of additional telomeric proteins and protein complexes are responsible for maintaining this unique telomeric DNA structure.[748-750] Highlighted here are the shelterin complex, telomerase, and CST1 and RTEL1 enzymes involved in telomere elongation and replication. Patients with dyskeratosis congenita have mutations in one of eight gene products participating in telomere maintenance (highlighted in color; mutations in the telomerase complex are TERT, TERC, DKC1, NHP2, and NOP10; mutations in the shelterin complex are TIN2; mutations in enzymes involved in the replication of telomeres are CTC1 and RTEL1. **D**, Telomerase is a ribonucleoprotein complex. It uses its RNA component, TERC, as a template to synthesize telomeric repeats on the 3′ end of telomeres, thereby elongating the ends of chromosomes (see also Box 7-10).

Continued on following page

AD DC through a candidate gene approach. Telomerase RNA, or the *TERC* component, which along with TERT forms the core of the telomerase enzyme, also associates with the four proteins present in H/ACA-class RNPs, including dyskerin, NOP10, and NHP2 (telomerase RNP complex; see Fig. 7-10, C). Dyskerin, TERT, and *TERC* were the three components identified in purified active telomerase.[232]

The measurement of telomere length has become a widely used screening test to identify patients who have BMF due to DC. Several methods are available that provide this type of information (for review, see Aubert et al, 2012,[754] and Vera and Blasco, 2012[755]). Although the methods in general produce similar results, individual measurements are difficult to compare. Methods most frequently used clinically include the measurement of telomere restriction fragment (TRF) lengths; PCR amplification of telomere repeats; and FISH, quantitative FISH (Q-FISH), and flow FISH, which are based on digital microscopy and flow cytometry, respectively (see Fig. 7-10, *E*).

TINF2. Heterozygous mutations in *TINF2* represent the second most frequent cause of DC, after *DKC1* mutations.[211,212] *TINF2* encodes TIN2, one of the six



Clinically Most Frequently Used Methods for Telomere Measurements

Method	Approach	Advantages	Drawbacks
Telomere restriction fragment (TRF)	Southern blot hybridization using genomic DNA and probes against telomeric repeats or single-copy gene probe • Quantifies average telomere length per sample (i.e., total peripheral white blood cells)	• Well-known and widely used technique • Simple and relatively cheap	• Difficult to quantify • Requires many cells (~1 million) • Subtelomeric polymorphisms influence results
Telomere measurement by PCR	• Measures ratio of telomere repeat copy number to single-copy gene number • Quantifies average telomere length per sample	• Simple • Fast • Only little DNA required • A high throughput analysis possible • Can use archived DNA	• Very sensitive to quality of DNA
Flow FISH	• Telomere fluorescence in individual interphase cells using flow cytometry (FACS) • Quantifies average telomere length per cell in interphase nuclei	• Simple • Quantitative • Reproducible • Accurate • Can determine lineage-specific telomere lengths	• Restricted to single-cell solution • Requires live cells • Requires expensive and technically demanding equipment
Quantitative FISH (Q-FISH)	• Fluorescence microscopy to determine individual telomere lengths • Fluorescence after hybridization of metaphase spreads with a fluorescent PNA telomeric probe	• Measurement of telomere length of each individual chromosome • Allows quantification of "signal-free ends" • Qualitative analysis of telomeres	• Labor intensive and time consuming • Requires expensive and technically demanding equipment • External calibration is difficult • Requires dividing cells

E

Figure 7-10, cont'd E, Graphic illustration of the telomeric regions detected using the most frequently used telomere measurement methods. Telomere length measured by terminal restriction fragment includes subtelomeric DNA and telomeric repeats of the telomere. Both the quantitative fluorescent in situ hybridization and flow fluorescent in situ hybridization techniques use probes that are specific for pure telomeric repeats. Quantitative polymerase chain reaction compares amplification of pure telomere reads using telomeric primers (green arrows). The table below summarizes the different methods and their advantages and disadvantages. *(B, Tungsten shadow-cast visualization of a mammalian telomeric T loop using transmission electron microscopy courtesy of Jack Griffith, Department of Biochemistry, University of North Carolina, Chapel Hill, N.C.; E, Figure modified from Aubert G, Hills M, Lansdorp PM: Telomere length measurement: caveats and a critical assessment of the available technologies and tools.* Mutat Res *730, 59–67, 2012; Table modified from Vera E, Blasco MA: Beyond average: potential for measurement of short telomeres.* Aging [Albany, N.Y.] *4:379–392, 2012.)*

components of the shelterin complex, which interacts with telomere DNA repeats and protects the ends of chromosomes from degradation and from being recognized by the cell's DNA repair machinery (see Fig. 7-10, C).[233] TIN2, along with another shelterin component, TPP1, is important in recruiting telomerase to its site of action at the telomere.[243] TIN2 also associates with a protein called HP1-gamma, which binds to telomeres in S phase and is important in cohesion, the physical pairing of sister chromatids by association with proteins called cohesions.[244] The HP1-gamma binding site in TIN2 is specifically required for cohesion of sister telomeres, and mutations in this site can affect telomere length maintenance.

TCAB1. Two unrelated cases have been reported where DC was caused by compound heterozygous mutations in *TCAB1*.[245] TCAB1, also known as WDR79 and WRAP53, contains WD40 repeats and binds to the CAB box, a motif found in scaRNAs and TERC (see Figs. 7-10, C and 7-12, C). Binding of TCAB1 is necessary for localization in Cajal bodies, the nuclear sites of assembly of telomerase and scaRNAs.[246] Telomerase assembly in Cajal bodies is important in the translocation of telomerase to its site of action at the telomere, and TCAB1 inhibition leads to telomere shortening.[210]

CTC1. Patients with biallelic mutations in *CTC1* (conserved telomere component 1) present with a variable set of abnormalities, including some characteristic features of DC.[247,248] CTC1 forms a complex with two other proteins, Suppressor of cdc ThirteeN 1 (STN1) and TElomeric pathways with stN1 (TEN1). This complex is known as the CST telomere-capping complex (see Fig. 7-10, C). CTC1 and STN1 stimulate DNA polymerase primase by binding single-stranded DNA, suggesting that the complex may be involved in priming telomeric C-strand synthesis.[249] The corresponding complex in yeast is involved in maintaining telomeric DNA integrity. CTC1 may have a general role in DNA metabolism rather than a specifically telomeric one.

RTEL1. Both homozygous and heterozygous mutations in *RTEL1* have been described in DC patients.[250,251] RTEL1 is a helicase originally identified in a screen of genes that affect telomere length.[252] RTEL1 plays an essential role in maintaining telomere length and genome stability and is an antagonist of homologous recombination. It has recently been shown that RTEL1 is essential for the disassembly of telomeric T loops; without proper disassembly telomere loss occurs because of the action of the SLX4 nuclease complex, which resolves the T loop as a circle.[253] G-quadruplex structures at the telomere are a major source of telomere fragility in *RTEL1*-deficient cells.

Other Genes. For about 50% of patients in whom DC and BMF are diagnosed, the mutations or the genes mutated have not been identified. Like patients with DC and BMF caused by mutations in known genes, most of these patients, but not all, also have very short telomeres, suggesting that the affected gene or genes participate in the same pathway.

Unraveling of the molecular pathology of DC has greatly advanced our understanding of the disease. The finding that all forms of DC in which the pathogenesis is understood are caused by disruption of telomere maintenance highlights the importance of telomeres in the disease (see Fig. 7-9). Figure 7-11 summarizes our current model of the pathogenesis of DC.

Dyskeratosis Congenita Gene Mutations

Mutations in telomere maintenance genes that have been found in patients with DC are listed on the comprehensive Telomerase Database, which is updated regularly.[254]

***DKC1* Mutations.** The mutations in the *DKC1* gene that cause DC are mainly single–amino acid missense mutations[255] (Fig. 7-12, *A*) and can be inherited or occur de novo. The *A353V* mutation is the most frequent de novo *DKC1* mutation and is found in approximately 40% of patients with DC and *DKC1* mutations.[215] *DKC1* mutations are not randomly distributed but are concentrated in the N-terminal region of dyskerin. The crystal structure of the archaeal homologue of the H/ACA RNP complex, the Cbf5-Nop10 complex,[256,257] has enabled modeling of human dyskerin. In this model most of the residues mutated in cases of DC are tightly clustered in or near the PUA domain, which is predicted to bind H/ACA RNA, including *TERC* RNA (see Fig. 7-12, *B*). The mutations would thus be expected to decrease binding of the cognate RNA and lead to instability. Only two mutations have been found in the TruB catalytic domain, one of which, S121G, is located three residues from the essential aspartate required for pseudouridylation and, interestingly, is associated with a severe form of DC known as Hoyeraal-Hreidarsson syndrome (HHS, MIM 300240). The absence of mutations that would predict a "null" allele, such as frameshifts and nonsense mutations, suggests that a dyskerin null mutation is incompatible with life. In support of this notion, a dyskerin null mutation is embryonically lethal in mice.[258]

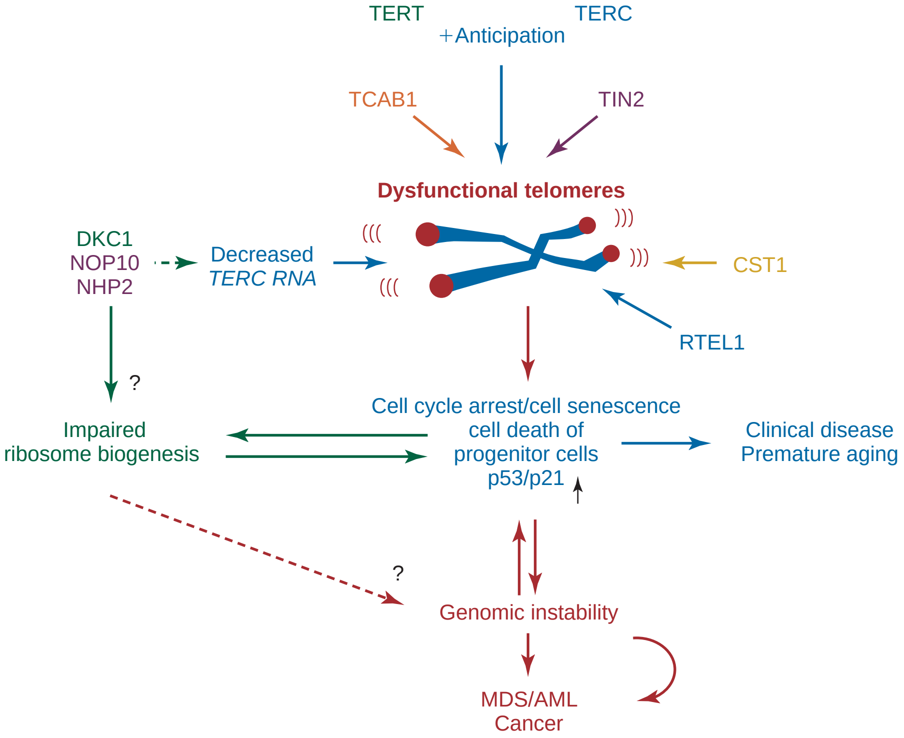


Figure 7-11 Model of the pathogenesis of disease in patients with dyskeratosis congenita. Our hypothesis is that excessive telomere shortening and dysfunctional telomeres play a central role in the pathogenesis of dyskeratosis congenita. Dysfunctional telomeres lead to cell cycle arrest, cell senescence, and cell death. In patients with *DKC1, NHP2,* or *NOP10* mutations, *TERC* RNA stability and accumulation are decreased, which leads to decreased telomerase activity and telomere shortening. Impaired ribosome biogenesis may also limit cell survival and proliferation. *TERC* and *TERT* mutations cause telomere shortening through haploinsufficiency. The inheritance of preshortened telomeres is the molecular basis of anticipation in autosomal dominant dyskeratosis congenita. *TCAB1* mutations prevent the recruitment of telomerase to the telomeres. RTEL1 and CTC1 are important for the proper replication of telomeres. Dysfunctional telomeres lead to genomic instability that may contribute to the cancer predisposition in patients with dyskeratosis congenita.

Figure 7-12 **A**, Mutations in the DKC1 gene. Schematic representation of the *DKC1* gene, below the schematic representation of dyskerin protein and its functional domains. A series of patient-derived mutations are shown in bold. An asterisk indicates recurrent mutations. The A353V mutation is shown in red; this mutation is a frequent de novo mutation and accounts for about one third of *DKC1* mutations. Mutations found in patients with the severe form of dyskeratosis congenita known as Hoyeraal-Hreidarsson syndrome are shown in purple. **B**, Clustering of pathogenic mutations in dyskerin. Crystal structure of the archaeal homologue of dyskerin. In this model the majority of residues mutated in cases of dyskeratosis congenita are tightly clustered in or near the pseudouridine synthase and archaeosine transglycosylase (PUA) domain, which is predicted to bind box H/ACA RNAs, including the TERC RNA. **C**, Schematic representation of the tertiary structure of the telomerase RNA (TERC). The pseudoknot and the CR4-CR5 domain are important for the association of TERC with the catalytic subunit TERT and for telomerase activity. Mutations found in families with autosomal dominant dyskeratosis congenita are shown, including two large deletions, one affecting the 5′ end and the other the 3′ end of TERC. **D**, Mutations in the *TERT* gene. Schematic representation of the 16 exons of the TERT gene, below the schematic representation of the TERT protein with its functional domains. Patient-derived mutations are shown in bold. Sequence variants of uncertain pathogenicity are shown in gray. Small deletions are indicated below the diagram. L1 and L2 are linker regions; Sf indicates a frameshift, which results in a premature stop codon X. The asterisk indicates recurrent mutations. **E**, *TINF2* mutations are tightly clustered in exon 6. Mutations at 5′ of the TRF1 binding site have been found in families with familial aplastic anemia, whereas mutations at 3′ of the TRF1 binding site are sporadic and cause a severe phenotype of disease with early onset, intrauterine growth retardation, cerebellar hypoplasia, immune deficiency, and retinal bleeding; this was previously described as Revesz syndrome but is in fact a severe form of dyskeratosis congenita. For a comprehensive listing of mutations see telomerase.asu.edu/diseases.html. *L1 and L2*, Linker regions; *NLS*, nuclear localization singnal; *Sf*, frameshift; *TruB and PUA*, pseudouridine synthase domains. *(**B**, Modified from Rashid R, Liang B, Baker DL, et al: Crystal structure of a Cbf5-Nop10-Gar1 complex and implications in RNA-guided pseudouridylation and dyskeratosis congenita.* Mol Cell *21:249–260, 2006.)*

The functional consequences of a subset of pathogenic *DKC1* mutations have been investigated in fibroblasts or mononuclear cells from patients with X-linked DC[208,259] and in XY mouse embryonic stem cells harboring a mutated *Dkc1* allele.[260,261] Analysis of fibroblasts or mononuclear cells from patients with X-linked DC showed a reduced level of *TERC* RNA and decreased telomerase activity, whereas analysis in mouse cells revealed that not only the level of *Terc* RNA but also the levels of other specific snoRNAs were affected and that overall pseudouridylation activity—in particular, site-specific pseudouridylation involving the affected guide snoRNA—was markedly decreased. Controversy continues as to whether X-linked DC is due solely to defective telomere maintenance or whether defective ribosome biogenesis contributes to the pathogenesis.[262] If the latter is the case, other relevant genes may not be effectively translated and thereby contribute to the pathophysiology (see later discussion of Diamond-Blackfan Anemia [DBA]).

Biochemical and structural studies of the assembly and structure of H/ACA RNPs, including telomerase, have so far failed to explain the structural and functional relationships in the effects of the *DKC1* mutations. Early in the biogenesis of H/ACA RNPs, prior to introduction of NAF1 and before assembly with the RNA component, dyskerin forms a tight connection with a protein SHQ1 and many *DKC1* mutations are in the region of dyskerin that interacts with SHQ1, suggesting that the mutations may affect biogenesis of the complex. It will be interesting to see if telomerase is preferentially affected by these mutations.[256,263]

***NOP10* Mutations.** Autozygous *NOP10* mutations have been identified in one consanguineous family. The mutation leads to replacement of a highly conserved arginine with tryptophan at amino acid position 34 (R34W).[226] The three affected family members were autozygous for the mutation. Heterozygous mutation carriers did not show obvious signs of disease but had shortened telomeres and decreased levels of *TERC* RNA in their peripheral blood cells. The inheritance of hypomorphic gene mutations may mimic a recessive inheritance pattern. The shortened telomeres and reduced levels of *TERC* RNA in heterozygous mutation carriers, however, suggest that both *NOP10* alleles are expressed codominantly. Whether the mutation affects the function of only telomerase RNP or also other H/ACA RNP complexes remains to be determined. In vitro experiments showed that the mutated NOP10 protein was not defective in the formation of the dyskerin-NAF1-NOP10-NHP2 tetramer that assembles with the nascent H/ACA RNA; rather, the mutation severely affected association with the H/ACA domain of TERC and a subset of other H/ACA RNAs.[264]

***NHP2* Mutations.** Two families with *NHP2* mutations have been reported. In one kindred affected children were homozygous for a Y139H mutation, while in the other the affected child was a compound heterozygote for a V126M and a mutation in the stop codon, X154RextX*52, resulting in an elongated protein.[265] In both cases parents were heterozygous and asymptomatic. Patients had low *TERC* levels and short telomeres. In vitro experiments showed that the V126M and the Y139H mutations impaired association with NOP10 and led to defects in H/ACA RNP assembly with all H/ACA RNAs tested, including *TERC*.[264]

***TERC* Mutations.** The *TERC* mutations found in patients with DC are shown in Figure 7-12, *C*. Investigation of family members revealed that in all patients with clinical manifestations of DC the *TERC* gene mutations were inherited. Many mutations are found in the pseudoknot domain of the molecule, a domain that mediates binding to the telomerase reverse transcriptase TERT and is essential for telomerase activity. Other mutations are found in the CR7 and H/ACA domains and affect the stability and nuclear accumulation of the *TERC* molecule. In many of these mutations it has been demonstrated that the mutations act by disrupting the secondary structure of the *TERC* molecule rather than by altering nucleotide sequences crucial for function[266-268]; this finding is in agreement with the fact that although the secondary structure of *TERC* is highly conserved among different species, the primary sequence is not.[269] Large gene deletions encompassing the *TERC* gene have been identified in two independent families with AD DC.[228,268] Along with the pathogenic mutations, which have been shown by several groups to severely reduce telomerase activity, there are two polymorphisms that are relatively frequent in people of African descent. These sequence changes, G58A and G228A, do not affect telomerase activity, and individuals carrying these sequence alterations have normal telomere length independent of the presence of BMF.[267,268,270]

The existence of large deletions and in vitro transfection studies led to the conclusion that haploinsufficiency of *TERC* is the mechanism underlying AD DC.

***TERT* Mutations.** Heterozygosity for nonsynonymous mutations in the *TERT* gene have been identified in individuals with aplastic anemia and short telomeres and also in individuals in whom pulmonary fibrosis was originally diagnosed.[177,229-231] A number of such mutations identified are shown in Figure 7-12, *D*. Mutations located in the N-terminal critical for binding of *TERC* RNA and within the central region of *TERT* defining the catalytic region of the reverse transcriptase impair telomerase activity to a variable degree. Mutations in the C-terminal region affect in vivo telomere synthesis after the assembly of a catalytically active enzyme.[271] Disease manifestations in families with *TERT* gene mutations are highly variable, and frequently disease does not segregate with the mutation in these families, indicating incomplete disease penetrance. No correlation has emerged between site of mutation and disease manifestations, but severity does increase in succeeding generations due to anticipation (see Box 7-11). Thus earlier generations may present as adults with pulmonary fibrosis or liver cirrhosis, whereas later generations may present as children with aplastic anemia or dyskeratosis congenita.[272] Interestingly, individuals with a de novo *TERT* gene deletion secondary to a large chromosomal deletion on chromosome 5p

Box 7-11 Anticipation

Genetic anticipation occurs when an inherited disease develops at increasingly younger ages or with increased severity in each succeeding generation. Thus if the disease develops in the offspring of a patient, it will tend to do so at an earlier age and display more severe clinical manifestations than in the parent. Disease anticipation is found in patients with autosomal dominant dyskeratosis congenita and is caused by the inheritance of increasingly shorter telomeres in subsequent generations.

(5p– syndrome, cri du chat syndrome) show accelerated telomere shortening but no clinical features characteristic of DC.[273] In contrast, biallelic *TERT* gene mutations have been identified in patients with classic manifestations of DC and in one individual with HHS, which suggests that the mutant alleles are expressed codominantly and the residual telomerase activity determines the clinical phenotype.[274,275] Biallelic *TERT* or *TERC* null mutations have never been described, suggesting that in contrast to mice, complete lack of telomerase activity is not compatible with life in humans.

***TINF2* Mutations.** *TINF2* mutations causing DC are strikingly clustered in the TIN2 protein (see Fig. 7-12, *E*).[211,212] Two thirds of the mutations affect a single amino acid residue, Arg282, changing it to a histidine or cysteine residue. Nearly all of the other identified mutations affect the same small region of the protein, encoded in exon 6. In vitro experiments have shown that TIN2, along with TPP1, is involved in recruitment of telomerase to telomeres,[276] and overexpression of the pathogenic TINF2 mutants disrupts the association between TIN2 and telomerase. Intriguingly the cluster of mutations in TIN2 overlaps with the HP1-gamma binding site in the protein that is essential for cohesion, the physical association of newly replicated telomeres.[244] It has been speculated that telomere cohesion may be necessary for efficient telomere elongation by the dimeric telomerase enzyme.[277]

***TCAB1* Mutations.** Two unrelated cases of DC caused by *TCAB* mutations have been reported. In both families the probands were compound heterozygotes for single point mutations causing amino acid substitutions, F164L and R398 in one case and H367Y and G435R in the other.[245] All the affected amino acids are highly conserved. The mutations result in decreased accumulation of TCAB1 and its mislocalization in the cytoplasm rather than the Cajal body. This causes accumulation of *TERC* in the nucleolus rather than the Cajal body, which presumably affects the subsequent trafficking of telomerase to the telomere.[245] In keeping with this premise, iPSC from TCAB1 DC patients shows normal levels of telomerase activity but defects in telomere lengthening.[210]

***CTC1* Mutations.** Most patients are compound heterozygotes, and the mutations include missense, nonsense, frameshift, and inframe deletions and splicing mutations.[247,248] *CTC1* mutations have also been implicated in a rare syndrome known as Coats plus syndrome or cerebroretinal microangiopathy with calcifications and cysts.[278] Null mutations are never found on both alleles of a single patient, suggesting that some CTC1 activity is essential for life. The pathogenetic mechanism by which these mutations cause a DC-like phenotype is unknown. Telomere length is normal[248,279] or short.[247,278]

***RTEL1* Mutations.** Biallelic missense mutations are the major cause of the severe DC (HHS) caused by *RTEL1* mutations,[251,280] though dominant mutations have been reported.[250] Mutations are mainly missense but include a splicing mutation and a nonsense mutation. An Arg981Trp mutation is recurrent. Examination of patients' cells using an assay that measures telomeric circles demonstrated that levels of these circles are higher than in controls. RTEL1 is responsible for disassembly of T loops, which are produced during faulty processing of telomere ends and cause telomere shortening.[251,280] In mice a biallelic *Rtel1* deletion is not compatible with life,[252] and no biallelic null mutations have been indentified in humans, suggesting that some RTEL1 function is essential. No defects in homologous recombination, which also involves RTEL1, have been found.

Genotype-Phenotype Correlation

The disease phenotype of patients with DC is highly variable and is influenced by the gene mutated, the pattern of inheritance (X-linked, autosomal dominant, or autosomal recessive), the nature of the mutation, and the history of inheritance (number of generations that the mutations have been passed on to). A distinctive feature of DC is that clinical manifestations differ with the age of disease onset (see Fig. 7-13).

***DKC1* Mutations.** The severity of disease in individuals with X-linked DC varies from hardly detectable to a severe form (HHS; see later) that causes death in early childhood (see Fig. 7-12, *A*). *DKC1* maps to the X chromosome, so the majority of affected individuals are therefore males. The most frequent clinical manifestation is classic DC with mucocutaneous findings in early childhood and progressive BMF in adolescence.

Female carriers of the *DKC1* mutation rarely show signs of hematologic disease. Cutaneous manifestations may be found in female carriers but are usually mild. Female carriers of X-linked DC show a phenomenon known as skewed or biased X-inactivation. In females, inactivation of one X chromosome must occur at random early in development to achieve the same dosage of X-linked genes as in male cells. When X-inactivation has been established in a particular cell, it is faithfully passed to all progeny. In women, tissues are therefore a mosaic in which half the cells have the active maternal and half the active paternal X chromosome. In female carriers of DC, blood consists entirely of cells in which the X chromosome containing the normal dyskerin gene is active[204,205]; this finding indicates that after random X-inactivation, cells with wild-type dyskerin have a growth or survival advantage (or both) and outgrow mutant cells. Whether this outgrowth takes place in embryogenesis or childhood and whether all tissues are affected are not known. Telomere length in peripheral blood cells in female DC

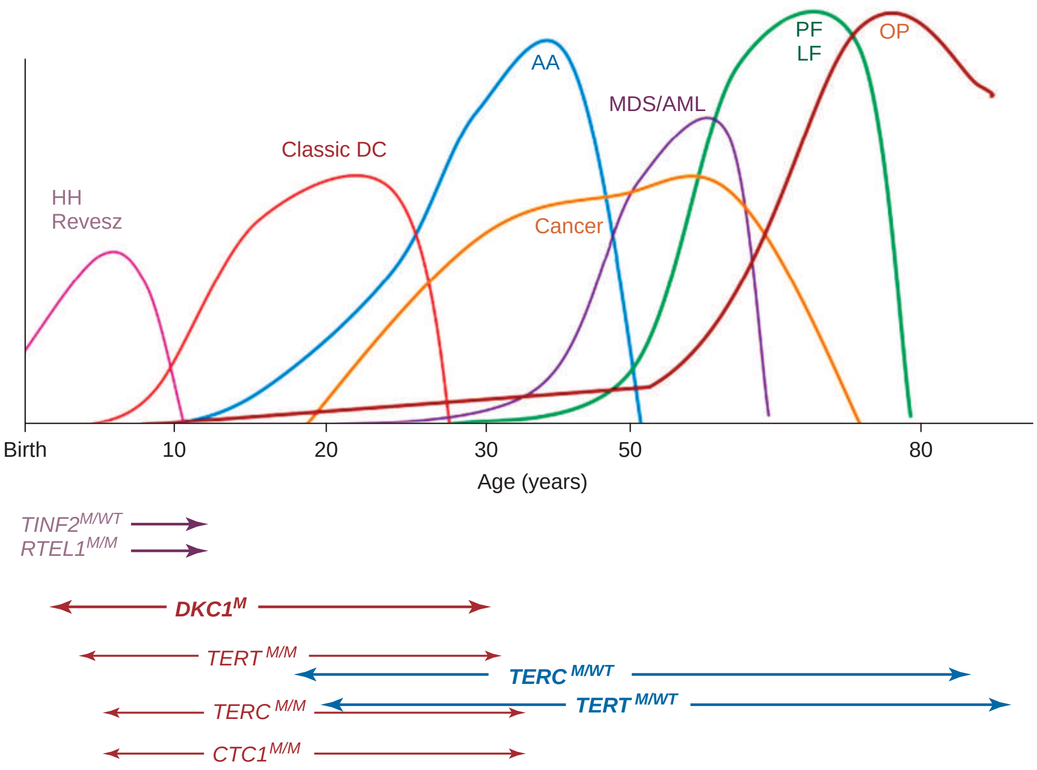

Figure 7-13 Clinical presentation of dyskeratosis congenita differs with age. The most severe forms of the disease, Hoyeraal-Hreidarsson syndrome and Revesz syndrome, manifest in early childhood and are mainly caused by *TINF2*, *RTEL1*, and *DKC1* mutations. Dyskeratosis congenita with the classic cutaneous features occurs in the teens and 20s and is mainly caused by *DKC1* mutations or homozygous *TERT*, *TERC*, or *CTC1* mutations. Aplastic anemia in the adolescent and young adult as well as pulmonary fibrosis and liver fibrosis and osteoporosis later in life are mainly caused by heterozygous *TERC* and *TERT* gene mutations. The risk of cancer and leukemia is highest in the young adult with moderate to severe disease.

carriers varies from within normal limits to very short.[163] Neither MDS nor MDS/AML has been described in a female *DKC1* mutation carrier. Whether female carriers are at increased risk for the development of cancer in other organs remains to be determined. Biased X-inactivation can be used to determine whether DC in a family is X-linked.

***TERC* Mutations.** The clinical phenotype in patients with AD DC caused by *TERC* gene mutations is usually mild. Analysis of family members of individuals with AD DC showed that mutation carriers frequently have only subtle signs of BMF but lack the mucocutaneous features of classic DC (atypical DC; see also Fig. 7-7). Interestingly, the only patient reported to be a compound heterozygote for two different *TERC* gene mutations showed signs of classic DC and early onset of disease, whereas family members with only one of the two mutations did not.[281] *TERC* gene mutations were identified in a subset of adult patients in whom familial or acquired idiopathic aplastic anemia was originally diagnosed and in patients in whom idiopathic pulmonary fibrosis was originally diagnosed.[177,282-284] Investigation of family members revealed that in all patients the *TERC* gene mutations are inherited and that all mutation carriers have short (<10th percentile) or very short (<1st percentile) telomeres. However, short and very short telomeres were additionally found in individual family members who did not carry the mutation and had no signs of disease.[285] *TERC* gene mutations were likewise identified in some patients with cytopenic MDS or MDS/AML.[282,284] The mutations identified were associated with reduced telomerase activity in vitro and very short telomeres in the mutation carriers with BMF. The presence of *TERC* gene mutations in patients in whom pulmonary fibrosis, aplastic anemia, MDS, or MDS/AML was originally diagnosed indicates that the underlying problem in these patients is the pathology of DC and that the variable expressivity and penetrance of the clinical manifestations in DC lead to a much broader clinical picture than originally anticipated when investigating only individuals with classic DC. Interestingly, *TERC* gene alterations were rarely found in children with aplastic anemia or MDS in the absence of a family history, consistent with the later onset of disease in individuals with AD DC.[196] Pulmonary fibrosis and liver cirrhosis were frequent and sometimes even the first clinical finding in individuals or families with DC and *TERC* gene mutations.

Anticipation. AD DC is one of a small number of diseases that show genetic anticipation (i.e., the disease becomes more severe and has an earlier age at onset in later generations). Anticipation became apparent when asymptomatic parents of affected individuals were found to also have *TERC* gene mutations (see Box 7-11).[228,286] In several cases, examination of these asymptomatic

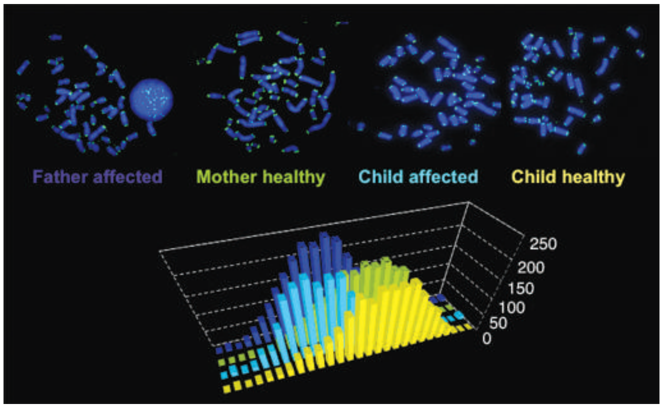

Figure 7-14 Inheritance of preshortened telomeres in a family with autosomal dominant dyskeratosis congenita due to a *TERC* gene deletion. Metaphase spreads of peripheral blood lymphocytes. The red signals at the end of chromosomes show the telomeric repeats hybridized to a fluorescent probe. Below, the graphic representation of the telomere length distribution of each family member. Note that both the affected and the nonaffected child have inherited preshortened telomeres; according to their young age their telomeres should be longer than the telomeres in their parents. *(From Goldman F, Bouarich R, Kulkarni S, et al: The effect of TERC haploinsufficiency on the inheritance of telomere length.* Proc Natl Acad Sci U S A *102:17119–17124, 2005.)*

parents revealed that they had signs of mild anemia, such as raised mean corpuscular volume. In other pedigrees, anemia develops in the parents at an older age than in the children. The mechanism of anticipation appears to be that telomere shortening increases in later generations carrying a defective *TERC* allele.[285,286] Figure 7-14 shows the inheritance of preshortened telomeres in a nuclear family with AD DC caused by a *TERC* gene deletion. Thus AD DC develops if an individual inherits a defective *TERC* or *TERT* allele and shortened telomeres. It is not known how many generations are needed to produce telomeres short enough to cause the disease. Studies in individuals with a de novo deletion of 5p that includes the *TERT* gene (5p– syndrome) indicate that in the first generation with *TERT* haploinsufficiency, telomere shortening is minimal.[273] Interestingly, in individuals with DC and BMF, the telomeres are all equally short, suggesting that there is a minimal length of telomeres required for a progenitor cell to contribute to the peripheral blood cell pool.[273,285]

***TERT* Mutations.** Nonsynonymous mutations, small deletions, and splice-site mutations in the telomerase reverse transcriptase *TERT* gene have been identified in individuals in whom aplastic anemia with short telomeres was diagnosed and in individuals in whom pulmonary fibrosis was diagnosed,[177,229,287] indicating that *TERT* gene mutations may account for cases of atypical DC. Anticipation has also been described in families with AD DC secondary to *TERT* gene mutations.[229] Individuals with heterozygous *TERT* gene mutations rarely have the classic form of DC; the majority have atypical DC. Pulmonary fibrosis is a frequent finding in patients and families with atypical DC caused by *TERT* gene mutations. Mutation carriers with no signs of disease (silent DC) are often found in families with heterozygous *TERT* gene mutations. Whether telomere length may identify silent *TERT* gene mutation carriers remains to be determined. Although one would expect that the disease in AD DC secondary to *TERC* or *TERT* mutations would be similar, initial family studies indicate that penetrance and expressivity differ in families heterozygous for *TERC* or *TERT* gene mutations. The most likely explanation is that TERC or TERT is limiting for different tissues and that expression of a functional TERT protein is regulated differently from regulation of *TERC* gene expression. Biallelic *TERT* gene mutations may lead to the classic manifestations of DC and have also been identified in one individual with HHS, which suggests that the mutant alleles are expressed codominantly and that residual telomerase activity determines the severity of the clinical phenotype.[274,275] Biallelic null mutations of *TERT* or *TERC* have never been described, suggesting that in contrast to mice, in humans complete lack of telomerase activity is incompatible with life.

***NOP10* and *NHP2* Mutations.** The one family with DC due to a homozygous R34W mutation in NOP10 contained three affected children who all showed the classic mucocutaneous features of DC.[226] Only one of the children had BMF. Affected individuals had very short telomeres and low TERC levels, whereas heterozygous family members were asymptomatic but did have shorter than normal telomeres and lower levels of TERC than healthy controls. Whether the lack of BMF in two of the three affected children is due to different genetic backgrounds or mosaicism due to mutations in bone marrow cells is not known. Two individuals with DC due to biallelic mutations in *NHP2* have been reported.[265] One, who was a homozygote, had nail dystrophy, thrombocytopenia, and mental retardation, while the other, a compound heterozygote, followed a classic DC course with pancytopenia at 12 years.

***TINF2* Mutations.** Patients with *TINF2* mutations are amongst the most severely affected of all DC patients.[211,212,288,289] Most patients present in infancy with very short telomeres and often with features of HHS or Revesz syndrome (retinopathy as well as pancytopenia, cerebellar hypoplasia, and developmental delay). *TINF2* mutations are dominant in that only one allele is mutated, but they are generally sporadic in that they are due to de novo mutations, patients being so severely affected that they do not live to reproduce (see also Fig. 7-12, *E*).

***TCAB1* Mutations.** Two unrelated cases of DC due to compound heterozygous TCAB1 mutations have been reported. Both patients had a classic DC presentation, with the mucocutaneous triad and BMF.[245]

***CTC1* Mutations.** Patients with *CTC1* mutations present with a variety of abnormalities, which include many of the characteristic DC features.[247,248] *CTC1* mutations are also found in patients diagnosed with Coats plus syndrome or cerebroretinal microangiopathy with calcifications and cysts.[278] This is a rare multisystem disorder characterized by progressive intracranial calcifications and leukoencephalopathy, often with the development of intracranial cysts. Retinopathy, BMF, and, less frequently, nail dystrophy, graying or sparse hair, and skin pigmentation abnormalities are also seen. Many of these features overlap with those seen in patients with DC, and *CTC1* mutations have in fact been found in patients diagnosed with DC. Patients included those with BMF or some of the mucocutaneous DC features with presence or absence of intracranial calcifications and retinopathy. Telomere length has been reported as short or normal.[248]

***RTEL1* Mutations.** A group of seven families with biallelic mutations in *RTEL1* was reported by Walne and colleagues.[251] These patients had a consistent type of HHS, characterized by BMF, cerebellar hypoplasia, microcephaly, intrauterine and extrauterine growth retardation, B-cell immunodeficiency, and early death. Abnormal skin pigmentation was absent, and less than half the patients had nail dystrophy or leukoplakia. Le Guen and colleagues[280] reported on three patients from two families with HHS. Affected children in both families had compound heterozygosity for an *RTEL1* missense mutation.[280] Fibroblasts from children with RTEL1 gene deletions showed telomere shortening, increased spontaneous 53BP1 foci formation, anaphase bridges, sister telomere losses, and terminal deletions. Ballew and associates[250] described three families with *RTEL1* mutations. One kindred had HHS due to biallelic *RTEL1* mutations. The other two families harbored heterozygous *RTEL1* mutations.[250] In one family, two children with HHS inherited an *R1010X* nonsense mutation from their healthy mother. The other patient was a man in his 20s who was diagnosed with DC-like disease and had an *A645T* mutation. Thus it seems that biallelic *RTEL1* mutations are a common cause of HHS, and time will tell how frequently dominant mutations are found in BMF syndromes.

Molecular Diagnosis of Dyskeratosis Congenita

Currently, molecular diagnostic tests are not routinely performed as the first line of investigation for DC because they are expensive, labor intensive, and informative in only half of patients. Nevertheless, identification of pathogenic mutations in one of the DC genes is the only way to definitively establish the diagnosis of DC. Furthermore, molecular diagnostic tests enable the identification of mutation carriers, facilitate prenatal diagnosis for an existing pregnancy, and allow preimplantation genetic diagnosis for partners identified as mutation carriers. In addition, because the clinical manifestations, severity of disease, prognosis, and response to treatment may vary, depending on the affected gene and the nature of the individual mutation, molecular diagnostic tests may also influence medical management not only for the individual carrying the mutation but also for unaffected family members. Currently, an educated candidate gene approach, in which the gender ages at disease onset and family history of the affected individual are taken into account, is used to identify the affected gene (see also Fig. 7-13). In an affected male, after exclusion of the most frequent *DKC1* mutation (A353V), it might be necessary to perform a mutational screen of the entire coding sequence of all three DC genes (usually only *TERC* and *TERT* in an affected female). For *TERC* and *TERT* the screening methods should include techniques that will detect large deletions. In addition to the large number of mutations in DC genes associated with DC, a number of nonpathogenic mutations and mutations of unknown pathogenic significance have been identified. Determining the pathogenicity of a particular mutation may be difficult.[290]

Telomere measurement in peripheral blood cells and peripheral blood lymphocytes has emerged as a sensitive screening tool for DC in patients with BMF.[162,163] Whether telomere measurements performed on peripheral blood cells may also identify DC mutation carriers or individuals with DC but nonhematopoietic disease manifestations is controversial.[162,163,248,291]

Diseases Related to Dyskeratosis Congenita

Idiopathic Aplastic Anemia. A proportion of patients with idiopathic aplastic anemia or hypoplastic MDS were found to have mutations in *TERC* or *TERT*.[282-284] These patients therefore have AD DC. The prevalence of *TERC* mutations among individuals in whom idiopathic aplastic anemia or hypoplastic MDS is diagnosed appears to be between 2% and 10%.[163] *TERC* mutations are rare in children with severe aplastic anemia or MDS consistent with later onset of the AD disease.[196] Because parents are often asymptomatic as a result of the anticipation phenomenon and because of incomplete penetrance of *TERC* and, in particular, *TERT* gene mutations, a family history is often not apparent and a diagnosis of idiopathic aplastic anemia or idiopathic MDS is made. As a consequence patients below the age of 50 years with acquired aplastic anemia or hypoplastic MDS are now routinely screened for telomere length to identify those who have BMF due to DC. Due to natural telomere shortening with age, telomere length measurements are less sensitive for the identification of patients with underlying DC mutations who are older than 50 years.

Hereditary Pulmonary Fibrosis. Pulmonary fibrosis, especially in patients with AD DC, may be an initial and sometimes prominent feature of those with atypical DC. Families with hereditary pulmonary fibrosis of adult onset should be investigated for an underlying *TERT* or *TERC* gene mutation.[177,178] The exact pathogenesis of pulmonary fibrosis in patients with DC is not understood.[179] Families with pulmonary fibrosis and aplastic anemia almost always have an underlying *TERT* or *TERC* gene mutation. Interestingly, pulmonary fibrosis is frequently found in the older generation, whereas aplastic anemia manifests earlier in life and manifests in subsequent generations (see also Fig. 7-8).[292] Thus pulmonary fibrosis in the 50s in the first generation and aplastic anemia in the 20s not only illustrates disease anticipation but also the unique features of age-specific disease manifestation characteristic for AD DC (see Figs. 7-8 and 7-13).

Hoyeraal-Hreidarsson Syndrome. Hoyeraal-Hreidarsson syndrome (HHS; MIM 300240) is a rare, severe variant of DC that presents in early childhood. It is characterized by intrauterine growth retardation, microcephaly, cerebellar hypoplasia, mental retardation, progressive combined immune deficiency, and aplastic anemia.[293,294] Delayed myelination and hypoplasia of the corpus callosum have been described in patients with HHS.[295] HHS may be caused by a mutation in the *DKC1* gene (see Fig. 7-12, *A*).[296] It is also notable that several cases of HHS are due to the recurrent mutation (A353V) that is responsible for a third of the X-linked *DKC1* cases.[215] In addition, HHS has been found in one individual autozygous (homozygosity in a consanguineous family) or compound heterozygous for a *TERT* gene mutation[290] and in an individual heterozygous for a *TERT* gene mutation and anticipation, suggesting that HHS may also be a consequence of a severe telomerase defect alone. In fact, most, although not all, of the HHS patients have very short telomeres at the time of diagnosis.[215,291] Recently biallelic mutations in *RTEL1* have been identified as responsible for a proportion of patients with HHS with short telomeres.[250,251]

Revesz Syndrome. The association of progressive bilateral exudative retinopathy (Coats retinopathy), intrauterine growth retardation, fine sparse hair, fine reticulate skin pigmentation, ataxia secondary to cerebellar hypoplasia, cerebral calcifications, extensor hypertonia, and progressive psychomotor retardation with progressive BMF and death in early childhood is also known as Revesz syndrome (MIM 268130), another severe form of DC.[297] Similar to patients with HHS, individuals with Revesz syndrome have very short telomeres. *TINF2* exon 6 mutations have been identified in patients with Revesz syndrome.[211,212]

Ataxia-Pancytopenia Syndrome. Ataxia-pancytopenia syndrome is a BMF syndrome originally described with several similarities to severe forms of DC. In patients with this syndrome, BMF is associated with severe cerebellar hypoplasia and chromosomal instability without an increase after DEB or MMC testing.[298] MDS and MDS/AML with monosomy 7 are often associated with this syndrome.[298,299] A *TINF2* mutation and short telomeres were identified in one patient, suggesting that the ataxia-pancytopenia syndrome patients have severe DC, HHS, or Revez syndrome.[300]

Coats Plus Syndrome. Coats plus syndrome (MIM 612199), or cerebroretinal microangiopathy with calcifications and cysts, is caused by compound heterozygous mutations in *CTC1*. Many features of these related disorders overlap with those of DC. These features include hair, skin, and nail changes; anemia; thrombocytopenia; osteopenia; intracranial calcifications; exudative retinopathy; and developmental delay. Telomere length in individuals with *CTC1* mutations are more variable.[251]

Poikiloderma with Neutropenia. Poikiloderma with neutropenia (Clericuzio-type poikiloderma with neutropenia, MIM 604173) is a rare AR disease characterized by early-onset poikiloderma, pachyonychia, palmoplantar hyperkeratosis, skeletal defects, and noncyclic neutropenia.[301] The disease is caused by mutations n the *USB1* gene (alias C16orf57 and MPN1)[302,303] and shares some of the clinical characteristics with DC, including abnormal skin pigmentation (poikiloderma, seen in all of the patients), nail dystrophy, and neutropenia and sometimes other characteristics such as leukoplakia, epiphora, short stature, and pulmonary problems.[302] *USB1* encodes a protein that is essential for the processing and stability of U6 snRNA, a molecule with a crucial role in RNA splicing; whether USB1 also plays a role in telomere biology remains to be determined. Patients with poikiloderma with neutropenia have normal telomere lengths in their circulating blood cells.[302] It is therefore controversial as to whether poikiloderma with neutropenia should be included in the group of patients classified as having DC or rather represents a distinct disease category. Patients with poikiloderma with neutropenia have a predisposition to developing MDS and squamous cell carcinoma of the skin.[304]

Animal Models. Dyskerin is highly conserved throughout evolution in its role in rRNA modification and processing but only interacts with telomerase in vertebrates. Thus yeast mutants of Cbf5 show defects in rRNA processing, ribosome biogenesis, and growth; null mutations are lethal.[221] The dyskerin orthologue in *Drosophila* is Nop60B, also known as minifly, and null mutations are again lethal, while partial loss of functional mutations cause pleiotropic effects, including extreme reduction in body size, developmental delay, and reduced female fertility.[219,305,306] These effects have similarities to minute mutants in *Drosophila* , which are caused by ribosomal protein mutations.[307] They are also similar to features of DC, strengthening the idea that ribosomal defects may contribute to the spectrum of abnormalities in DC. In zebrafish, knockdown or mutagenesis of dyskerin or other H/ACA snRNP proteins (GAR1 or NOP10) leads to defects in ribosome biogenesis and p53-dependent inhibition of hematopoiesis without affecting telomerase activity, making extrapolation to the human disease difficult.[308,309]

In mice, models of X-linked DC have been hampered by the fact that laboratory mice have very long telomeres that do not become critically shortened in the presence of a compromised dyskerin protein. Nevertheless mutations that are copies of human *DKC1* mutations do cause increased DNA damage and defects in hematopoietic stem cell repopulation that are partially corrected by treatment with the antioxidant N-acetyl cysteine.[261,310] The most promising mouse models have involved deficiency of telomerase itself or defects in components of shelterin. Laboratory mice can thrive without either TERT or TERC, but after several generations of breeding, telomeres shorten and eventually mice show many of the features of DC, notably degenerative effects in tissues with high turnover such as hematopoietic cells, testicular cells, and cells of the skin and gastrointestinal tract.[311,312] In wild CAST/EiJ mice, which have shorter telomeres, haploinsufficiency for *Tert* and *Terc* genes causes DC-like features in early generations.[313-315] Defects similar to those in DC are also seen in mice lacking shelterin component Pot1b in combination with reduced telomerase activity. These mice show rapid telomere shortening, skin and nail defects, and fatal BMF.[316,317] Pot1b is a variant form of POT1 found in mice but not humans. These findings illustrate that the mouse can faithfully model telomere diseases and demonstrate the importance of dysfunctional telomeres in DC pathogenesis.

iPS Cells. iPS cells are pluripotent cells derived from differentiated cells such as fibroblasts by reprogramming with a cocktail of transcription factors.[130,318] They have been heralded as having the potential for tissue renewal and regeneration and are immediately useful as models for inherited diseases as they carry the patient's genome and can be cultured to undergo differentiation into many mature cell types. iPS cells have been isolated from DC patients with disease caused by *DKC1*, *TERC*, *hTERT,* and *TCAB1* mutations.[209,210] The efficiency of reprogramming was low compared with that found in other diseases, perhaps reflecting the fact that stem cell defects are one of the cardinal features of DC. In contrast to other cell lines obtained from patients with DC, iPS cell lines express telomerase activity and therefore allow the study of telomere dynamics in the disease that cannot be studied otherwise. Whether undifferentiated iPS cell lines derived in DC are able to maintain their telomeres over time is controversial and awaits further studies. Nevertheless iPS cells from DC patients are promising, powerful, and unique tools for studying human telomere biology and the molecular pathogenesis of DC. However, there is likely a long path before iPS cell technology fulfills its potential in tissue regenerative therapeutic approaches, the goal that makes this technology so attractive in BM research.[319]

Mechanism of Disease Pathogenesis in Dyskeratosis Congenita

Dysfunctional telomeres are the likely central theme in the pathogenesis of DC. Figure 7-11 summarizes our current model of the pathogenesis of disease in DC.

Clinical Management

Most of what we know regarding therapy and prognosis comes from our experience with patients with classic DC. Care must be taken when extrapolating such experience to all DC patients. The prognosis for patients with classic or severe DC is usually poor. In males with X-linked and sporadic DC, the median age at death was 20 years.[27] Patients with AD DC have milder disease with a better survival rate. Deaths were usually due to complications from aplastic anemia, BMT, pulmonary fibrosis, or cancer.[41]

Only identification of a pathogenetic mutation can confirm the diagnosis. Once confirmed, the family should be referred to a clinical geneticist familiar with new developments in DC for counseling and careful examination of family members. Genetic testing and possibly telomere measurement should be offered to all family members. Early diagnosis is important for correct management of hematologic complications; appropriate treatment of associated pulmonary, gastrointestinal, ocular, dental, and bone disease; identification of affected presymptomatic family members and unaffected family members or pregnancies that may serve as potential hematopoietic stem cell donors; and targeted cancer surveillance, not only in the patient with DC but also in mutation carriers.

Unfortunately, there is currently no consensus on how to manage patients with DC. Management depends on the age at diagnosis, the presence or absence of clinical signs, the gene affected, the molecular characteristic of the mutation identified, and possibly the telomere length. All patients with DC and hematologic manifestations should have a full hematologic assessment, including examination of bone marrow, and in anticipation of possible HSCT, HLA typing should be performed. Other investigations at diagnosis should include pulmonary evaluation and examination of the oropharynx and anal region; in females, cytologic examination of the vagina and cervical epithelium is needed. The prognosis and life expectancy of family members who have inherited only the short telomeres but not the gene mutation are unknown. Whether these family members should be excluded as potential sibling donors of an affected family member is also unknown.

Management of Hematologic Disease

Treatment of BMF in patients with classic DC is similar to that in patients with FA. Initially, in the absence of hematologic abnormalities or clinical and laboratory signs of mild BMF, monitoring of peripheral blood values might be sufficient. In the presence of hematologic abnormalities, yearly bone marrow examination should include a trephine biopsy and marrow aspiration for the examination of marrow cellularity and morphologic changes characteristic of MDS, as well as for cytogenetic examination by G banding and FISH analysis; testing should include probes that identify the most frequent cytogenetic abnormalities seen in patients with DC and progression to MDS or AML, or both (see earlier also). Plans for possible HSCT should be in place because hematologic complications may develop rapidly. With progression of BMF it will become necessary to increase the frequency of hematologic monitoring, and it may have to be individualized. The anabolic steroid oxymetholone can produce improvement in hematopoietic function. Approximately two thirds of patients with DC will respond to oxymetholone; in some cases this response can last several years and involve all lineages. Patients with DC may respond to a dose as low as 0.25 mg of oxymetholone/kg/day, which can be increased, if necessary, to 2 to 5 mg/kg/day.[320,321] Hematopoietic growth factors usually, if at all, have only a transient effect and should not be used in combination with androgens because of the risk of peliosis and splenic rupture.[320,321] Unlike idiopathic aplastic anemia, immunosuppressive agents such as antithymocyte globulin and cyclosporine are ineffective or only have a transient response in cases of DC and BMF.

The ultimate treatment of BMF is allogeneic HSCT. However, HSCT for DC has been associated with high morbidity and mortality rates, more so than in other BMF syndromes. Pulmonary and vascular complications are the major causes of death associated with HSCT in patients with DC.[176,322-324] Reduced-intensity nonmyeloablative fludarabine-based conditioning regimens with no or minimal irradiation are associated with lower toxicity and fewer complications.[325-328] Long-term survival and late complication rates after HSCT in patients with DC remain to be determined.

Management of DC patients with MDS or AML (or both) is even less standardized. The significance of transient clonal cytogenetic abnormalities is unclear, but if persistent or complex, such abnormalities usually predict a poor prognosis. Success is unlikely with early hematopoietic stem cell harvest for autologous transplantation at a later time because of the limited repopulating ability of the affected stem cells.

Management of Pulmonary Disease

There is currently no treatment of pulmonary disease in DC. Cigarette smoke is known to accelerate disease onset and severity. Thus patients with DC should refrain from smoking, avoid drugs with pulmonary toxicity (e.g., bleomycin), and have their lungs shielded from irradiation during BMT or cancer treatment. Pulmonary fibrosis in patients with DC does not respond to immunosuppressive therapy. Lung transplantation might be considered in individuals with otherwise mild manifestations of disease.[329]

Cancer Surveillance and Treatment

Patients with confirmed DC should avoid excessive exposure to ultraviolet light and use barrier sun creams. Avoidance of smoking and alcohol should be emphasized, particularly in patients with oral leukoplakia.[170,330] DC patients should also undergo regular dental and hygienist review to prevent early tooth loss and reduce the occurrence of leukoplakia. It is important to screen for malignant disease, especially of the gastrointestinal system. Management of malignant disease may be complicated by a number of factors. The diagnosis may be delayed in some cases because of malignant change occurring within an area of persistent leukoplakia, resulting in a delay in treatment. There is also a high potential for local recurrence and multiple cancers in these patients. In addition, the presence of BMF makes chemotherapy very difficult and can limit the indications for surgery. The mucosa also has high sensitivity to irradiation, which can lead to severe mucosal damage and may result in early termination of radiotherapy.

Management of oral malignant disease usually includes a regular review and biopsy of the premalignant hyperkeratotic lesion and surgical laser excision of any suspicious areas. Neoadjuvant radiotherapy or surgical resection of confirmed malignant tumors, along with ipsilateral node clearance with or without adjuvant radiotherapy in accordance with staging of the disease, is the mainstay of treatment.

Gene Therapy

HSCT may improve or cure hematologic disease in DC patients, but HLA-matched sibling donor cells are available for only a minority of patients; furthermore, immune reconstitution is often delayed. Gene therapy to correct hematopoietic stem cells followed by autologous transplantation might offer an attractive alternative for the treatment of hematologic disease in DC patients. Biased X-inactivation in female *DKC1* mutation carriers suggests that DC cells corrected by gene therapy are likely to have a selective growth and survival advantage. Indeed, gene transfer of *TERT* or *TERC* (or both) corrects the telomere defect in most DC cell lines.[331] However, as in many other IBMFSs, the few surviving hematopoietic stem cells might have already acquired secondary somatic and possibly oncogenic mutations, so correction by gene therapy could promote rather than prevent leukemogenesis in these patients. Interestingly, in rare patients with DC due to *TERC* gene mutations, gene reversion by mitotic recombination in hematopoietic stem cells leads to two normal copies of the *TERC* genes in the majority of circulating blood cells.[332] Revertant cells contribute to the myeloid and B lymphocyte lineages but were not detectable in T lymphocytes, suggesting that mitotic recombination occurred in a stem cell committed to myeloid and B-cell differentiation or that the selective advantage for gene revertant cells is less in T cells than in myeloid and B cells. Indeed, T cells are less severely affected by DC mutations (see also above) and have a longer survival time in circulation. Revertant mosaicism in DC seems to be less frequent than reported in FA and currently has only been described in DC patients with *TERC* gene mutation.[332] However, as in FA, DC revertant mosaicism might mask an inherited *TERC* gene mutation when genetic testing is performed in peripheral blood cells. DNA from skin fibroblasts or buccal swabs might have to be sent for genetic testing in patients with classic DC features but no BMF. Revertant mosaicism in patients with DC but no BMF powerfully illustrates the feasibility of gene therapy and shows that the restoration of a normal *TERC* gene in a single hematopoietic stem cell in these patients can restore blood cell production.

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome (SDS, MIM 260400) is a rare, recessive multisystem disorder characterized by exocrine pancreatic insufficiency, bone marrow dysfunction, and skeletal abnormalities, first described in the 1960s (Box 7-12).[333,334]

Clinical Manifestations

SDS is a IBMFS with an estimated incidence of 1 per 75,000 live births.[335] SDS is more commonly diagnosed in boys, with a male-to-female ratio of 1:7.[336] The major

Box 7-12 **Shwachman-Diamond Syndrome**

Shwachman-Diamond syndrome (MIM #260400) is a rare, recessively inherited bone marrow failure syndrome characterized by exocrine pancreatic insufficiency, bone marrow dysfunction (including increased risk for malignant transformation), and skeletal abnormalities.

TABLE 7-7 Major Clinical Features of Shwachman-Diamond Syndrome

Clinical Feature	Aggett (1980)[337]	Mack (1996)[341,†]	Smith (1996)[342]	Ginzberg (1999)[336]	Cipolli (1999)[338]	Kuijpers (2005)[340,‡]	Hashmi (2011)[339,§]	Total/ Average

Rib cage abnormalities	52%	32%		32%	92%		12%	35%
Short stature (<3rd percentile)	95%	67%		56%	85%	52%	76%	66%

[*] Hematologic abnormalities and exocrine pancreatic insufficiency are defining features of SDS, hence the 100% incidence of these findings.
[†] Short stature was defined as below the 5th percentile for height.
[‡] Severe neutropenia is less than 600/μL. Fifteen of 20 patients (75%) tested had *SBDS* mutations.
[§] Twenty-five of 31 patients (81%) had *SBDS* mutations.

clinical features associated with SDS have been defined in several large cohort studies; they are summarized in Table 7-7.[336-339,340-342] The two most recent studies included genotyping, which showed that approximately 80% of patients in these studies with clinically defined SDS had biallelic mutations of *SBDS*.[339,340] Whether patients without *SBDS* mutations have distinct clinical features is unclear, though one study suggested that patients with wild-type *SBDS* may have more severe hematopoietic disease but milder pancreatic dysfunction.[339]

Hematologic Abnormalities

Neutropenia is present in the majority of patients with SDS (range, 74% to 100%); severe neutropenia (as defined by an absolute neutrophil count [ANC] of less than 500/μL) was observed in a mean of 46% of patients (range, 23% to 67%; see Table 7-7). Neutropenia is intermittent in about two thirds of patients and chronic in the remaining one third. Although defects in neutrophil chemotaxis are present in most patients with SDS,[343] the clinical significance of this finding is unclear, since neutrophils are recruited to sites of infection.[344] Anemia is present in approximately 50% of cases and is usually associated with a low reticulocyte count and mild macrocytosis.[339] Thrombocytopenia is present in approximately 50% of cases, sometimes without concomitant neutropenia. Pancytopenia has been reported in 10% to 44% of patients. Presentation with or progression to severe aplastic anemia has been reported.[345-347] Defects in B-lymphocyte and/or T-lymphocyte function have been described, including impaired specific immunoglobulin response and altered CD4 or CD8 T-cell subsets.[348] Bone marrow findings are variable and nondiagnostic. Although bone marrow hypoplasia is common, normal or even increased cellularity has been reported.[336,337,339,342] Left-shifted granulopoiesis is common. Mild dysplastic changes are commonly seen and may fluctuate, but prominent myelodysplasia is uncommon and may suggest malignant transformation.

Transformation to MDS and AML

Similar to other congenital BMF syndromes, there is a strong predilection to develop MDS or MDS/AML in patients with SDS. Acquired clonal cytogenetic abnormalities are frequently seen; in a prospective study of 14 patients with SDS followed for a maximum of 5 years with annual bone marrow evaluations, clonal cytogenetic abnormalities were detected in 29% of patients.[349] Abnormalities of chromosome 7 are the most common and include monosomy 7, isochromosome 7q, and deletion of 7q. The clinical significance of these cytogenetic abnormalities is uncertain. In particular, isochromosome 7q appears to have a benign course with a low risk of transformation to MDS or MDS/AML.[349-351] Likewise, the loss of the long arm of chromosome 20 [del(20)(q11)], which is common in patients with SDS as an isolated chromosomal anomaly, is not associated with progression to MDS.[352,353] The reported rate of transformation to MDS/AML for patients with SDS is highly variable. One of the difficulties is the definition of early MDS in the presence of clonal hematopoiesis. In an observational study of 29 patients with SDS enrolled in the North American Severe Chronic Neutropenia Registry, two cases (7%) of MDS/AML were reported.[354] In contrast, no cases of MDS/AML were reported in 17 patients with SDS (representing 274 person-years of observation) in the National Cancer Institute IBMFS cohort study.[41] Finally, a cumulative incidence of MDS/AML of approximately 10% at 20 years of age was reported in a French study of 102 patients with SDS.[345] In this study, the severity of cytopenias at presentation correlated with risk of transformation. Of interest, in contrast to a prior report,[355] no increased male gender bias with respect to risk of MDS/AML transformation was observed in this study. The malignant clone

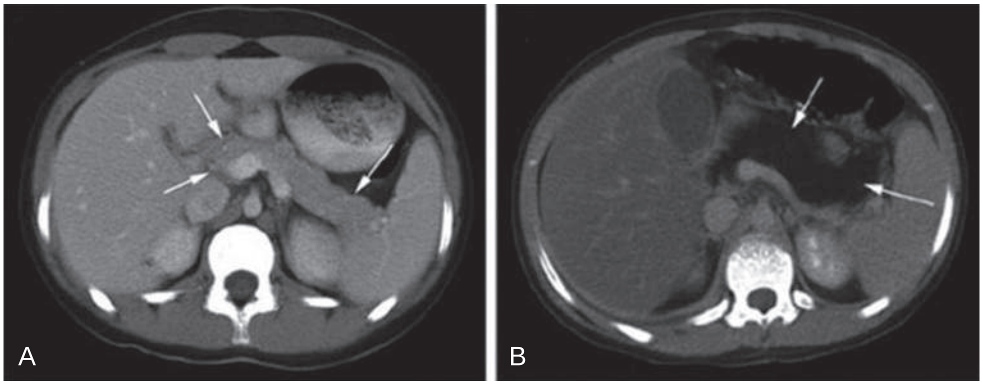

Figure 7-15 Fatty infiltration of the pancreas in Shwachman-Diamond syndrome shown by transverse computed tomography images of a normal individual (**A**) and a patient with Schwachman-Diamond syndrome (**B**). The density of the normal pancreas (arrows) is similar to that of the liver. In contrast, the density of the pancreas in the Schwachman-Diamond syndrome patient (arrows) is reduced, consistent with fatty infiltration. *(From Nijs E, Callahan MJ, Taylor GA: Disorders of the pediatric pancreas: imaging features.* Pediatr Radiol *35:358–373, 2005.)*

often displays complex cytogenetic abnormalities frequently involving chromosome 7.

Gastrointestinal Abnormalities

After cystic fibrosis, SDS is the most common cause of congenital exocrine pancreatic insufficiency. Patients classically present in early infancy with steatorrhea and failure to thrive. Pathologic analysis shows extensive fatty replacement of pancreatic acini with relative preservation of pancreatic ducts and islets of Langerhans.[337] Exocrine pancreas insufficiency can be assessed by measurement of serum trypsinogen, serum isoamylase, or fecal fat.[356] In addition, imaging of the pancreas may reveal characteristic fatty infiltration[357,358] (Fig. 7-15). For unclear reasons, the pancreatic insufficiency improves with increasing age in many patients; by 4 years of age, nearly 50% of patients no longer require pancreatic enzyme supplements.[341] Mild (2- to 3-fold) elevation of liver transaminases is often seen in patients younger than 2 years of age. It is usually of little clinical significance and tends to improve with age.[341]

Skeletal Abnormalities

Most patients with SDS have bony abnormalities, with rib cage abnormalities, metaphyseal dysostosis, and osteopenia being the most common features (see Table 7-7).[359,360] A recent report suggested that impaired osteoclast formation may contribute to the skeletal abnormalities in SDS.[361] Growth retardation also is common in SDS patients, but it is not thought to be secondary to malnutrition. Over half of patients with SDS are below the 3rd percentile for height at 1 year.[336,362] With adequate pancreatic enzyme replacement, most patients show a normal growth velocity but remain below or at the 3rd percentile for height.[336]

Miscellaneous Abnormalities

Many patients with SDS suffer from neurocognitive deficits and pyschosocial dysfunction.[363-365] Dental abnormalities are common.[366,367] While there are reports of endocrine abnormalities such as diabetes mellitus[337,341] and growth hormone deficiency in SDS,[368] a recent comprehensive analysis of 43 patients with SDS showed no consistent endocrine phenotype.[362] Cardiomyopathy has been reported in patients with SDS.[369] In a recent study of 105 patients with SDS (mostly with *SBDS* mutations), the incidence of cardiomyopathy was 6%.[370] An increase in other congenital heart disorders also was observed in this study.

Differential Diagnosis

Diagnostic criteria for SDS are outlined in Box 7-13[371] both exocrine pancreatic insufficiency and hematopoietic abnormality must be documented. Other features of SDS, including short stature or skeletal or hepatic

Box 7-13 **Clinical Diagnostic Criteria for Shwachman-Diamond Syndrome**

HEMATOPOIETIC ABNORMALITIES (at least one is required)
Neutropenia (<1500/µL); can be intermittent or chronic but must be documented on at least two occasions over at least 3 months
Anemia or thrombocytopenia below that for the age-adjusted norm documented on at least two occasions over at least 3 months
Tests that support the diagnosis but require corroboration:
Persistent elevation of hemoglobin F (on at least two occasions over at least 3 months)
Persistent red blood cell macrocytosis (on at least two occasions over at least 3 months), not resulting from other causes such as hemolysis or nutritional deficiency
EXOCRINE PANCREATIC INSUFFICIENCY* (one is required)
Reduced levels of pancreatic enzymes adjusted to age (serum trypsinogen, serum isoamylase, or fecal elastase)
Test that support the diagnosis but require corroboration:
Abnormal 72-hour fecal fate analysis
Reduced levels of at least two fat-soluble vitamins (A, D, E, or K)
Evidence of pancreatic lipomatosis by ultrasound, computed tomography scanning, or magnetic resonance imaging
*Other causes of pancreatic insufficiency should be excluded
ADDITIONAL SUPPORTIVE EVIDENCE OF Schwachman-Diamond syndrome
Bone abnormalities
Behavioral problems
Presence of a first-degree relative with Schwachman-Diamond syndrome

abnormalities, while supportive, are not required for the diagnosis. Genetic testing for *SBDS* mutations is merited because their presence confirms the diagnosis. However, their lack does not exclude the diagnosis, because in 10% to 20% of cases of clinically defined SDS, no mutations of *SBDS* are present.[339,340,372,373] Other causes of exocrine pancreatic insufficiency should be considered, including cystic fibrosis, which can be excluded by performing a sweat test. *Pearson syndrome* (PS, MIM 557000) is characterized by exocrine pancreatic insufficiency, sideroblastic anemia, vacuolization of hematopoietic cells in the bone marrow, and metabolic acidosis.[374,375] It is caused by deletions in mitochondrial DNA.[376] *Cartilage-hair hypoplasia* (CHH, MIM 250250) is characterized by short stature, metaphyseal dysostosis, cytopenias, and hypoplastic hair.[377] It is secondary to mutations of *RMRP* encoding the RNA subunit of the RNase mitochondrial RNA-processing (RMRP) complex.[378]

Genetic Characteristics

SDS is an AR disorder.[379] The gene responsible for SDS was identified by genetic linkage analysis.[372] Boocock and colleagues[372] reported that compound heterozygous mutations of the *SBDS* (Shwachman-Bodian-Diamond syndrome) gene located on chromosome 7 were present in the majority of patients with SDS. Most of these mutations resulted from gene conversion with a neighboring pseudogene (*SBDSP*). Subsequent studies have confirmed that *SBDS* mutations are present in 80% to 90% of clinically diagnosed cases of SDS.[339,340,345,373,380,381] The majority of mutations occur within exon 2 and are predicted to result in the production of a truncated protein. The genotypes p.Lys62X/Cys84fs and p.Lys62X;Cys84fs/Cys84fs are found in 60% and 6% of the patients, respectively. The remaining mutations are missense and nonsense mutations scattered throughout the protein. The majority of mutations result in a dramatic reduction in SBDS protein production.[345,372,373,382] However, patients carrying homozygous null alleles for *SBDS* have not been reported, suggesting that SBDS is essential for life. Consistent with this conclusion, mice lacking the murine orthologue of *SBDS* die in the early embryonic stage.[383] Interestingly, in the subset of patients who do not have *SBDS* mutations, SBDS protein expression in leukocytes is normal, indicating that other genetic mutations may be responsible for these cases of SDS.[373]

Recent studies suggest that there may be a spectrum of disease associated with *SBDS* mutations. Nishimura and colleagues[384] reported that two unrelated patients with neonatal spondylometaphyseal dysplasia carried compound heterozygous mutations of *SBDS*. Clinical features included severe metaphyseal dysplasia, platyspondyly, and neonatal respiratory failure, resembling spondylometaphyseal dysplasia of the Sedaghantian type. Likewise, *SBDS* mutations are present in a subset of patients diagnosed with asphyxiating thoracic dystrophy (Jeune syndrome).[385] Thus it is important to consider the diagnosis of SDS in newborns presenting with thoracic dystrophy.

There also is evidence that haploinsufficiency for *SBDS* may predispose to the development of aplastic anemia. Calado and colleagues[386] reported that 4 of 91 patients with apparently acquired aplastic anemia had heterozygous mutations of *SBDS*. Interestingly, affected patients had no evidence of exocrine pancreatic insufficiency or bony abnormalities but did have short stature. However, no *SBDS* mutations were found in another study of 96 Japanese children with aplastic anemia.[387] Similarly, parents and siblings of patients with SDS are not known to have an increased risk of BMF, although no controlled studies have been performed.

The *SBDS* gene encodes for a protein of 250 amino acids that is highly conserved throughout evolution. The primary function of SBDS appears to be to regulate ribosome biogenesis. Consistent with this observation, SBDS protein prominently localizes to the nucleolus of cells in a cell cycle–dependent fashion.[388] Current studies support a model in which SBDS cooperates with the GTPase elongation factor–like-1 (ELFL1) to facilitate final stages in the translational activation of ribosomes.[389-391,392] Specifically, SBDS and ELFL1 catalyze the removal of eukaryotic initiation factor 6 (eiF6) from the 60S ribosome subunit, allowing for its assembly into an actively translating 80S subunit.[389-391] Together, these observations place SDS in a growing list of bone marrow disorders caused by impaired ribosome biogenesis. SBDS has also been implicated in non–ribosome related functions that may contribute to disease phenotype. For example, SBDS stabilizes the mitotic spindle,[393] and loss of SBDS in hematopoietic progenitors in patients with SDS may contribute to the high rate of chromosomal abnormalities in SDS.

The mechanism for the increased susceptibility to MDS and MDS/AML in SDS is unclear. There is evidence that *SBDS* mutations disrupt hematopoiesis through both cell intrinsic and non–cell intrinsic mechanisms. Hematopoietic colony formation is reduced in the bone marrow of patients with SDS,[394] and inhibition of *SBDS* expression in primary hematopoietic progenitors results in impaired hematopoietic stem cell function[395] and erythroid differentiation.[396] These data are supported by the observation that hematopoietic cells with an increased expression of the SBDS protein as it occurs with i(7)(q10)[397] or with copy number–neutral loss of heterozygosity of 7q[398] outgrow SBDS hematopoiesis, explaining the benign nature of these specific chromosomal anomalies in patients with SDS. Interestingly, loss of 20q results in deletion of the *EIF6* gene whose product competes with SBDS.[399] On the other hand, bone marrow stromal cells from patients with SDS have reduced capacity to support hematopoietic cell growth.[394] Intriguingly, loss of SBDS in bone marrow stromal cells produces an MDS-like phenotype in mice.[400] Thus both altered hematopoietic progenitor and bone marrow stromal function may contribute to the increased rate of transformation to MDS/AML.

Clinical Management

The management of patients with SDS was summarized recently in an updated clinical consensus guideline.[371] Treatment of SDS includes pancreatic enzyme replacement and fat-soluble vitamins for pancreatic insufficiency. Regular assessments of exocrine pancreatic function are recommended because in approximately 50% of patients there is spontaneous resolution of steatorrhea with increasing age.[341] Blood levels of fat-soluble vitamins should be checked every 6 to 12 months.

Regular blood counts should be measured every 3 to 6 months to monitor for cytopenias. The role of surveillance bone marrow biopsies is controversial. Whereas i(7q) has questionable prognostic significance, other chromosomal abnormalities, in particular monosomy 7, are associated with poor outcomes and may be an indication for HSCT. Current guidelines suggest annual bone marrow biopsies for patients treated with G-CSF and biopsies every 1 to 3 years for patients with stable blood counts who are not receiving G-CSF.[371] For patients with severe neutropenia or neutropenia and persistent or recurrent infections, a trial of G-CSF treatment is warranted; response rates are generally high.[401] Similar to severe congenital neutropenia, current recommendations are that the dose of G-CSF should be titrated to achieve and maintain an ANC of 1000 to 1500/μL. As discussed in the section on severe congenital neutropenia, the association of G-CSF with malignant transformation is controversial and has not has been demonstrated to date. Nonetheless, patients with SDS should receive the lowest dose of G-CSF required to maintain an acceptable neutrophil count.

Allogeneic HSCT is the only curative therapy for SDS. It is generally reserved for patients with severe cytopenias, MDS with excess blasts, or frank leukemia. Only small case series of HSCT in patients with SDS are available. HSCT in patients with SDS is associated with increased regimen-related toxicity, in particular of the heart, lung, and liver. The pathobiology of this increased toxicity is not understood, although impaired cardiac function is present in some patients with SDS.[402] The French neutropenia registry reported a 5-year event-free survival rate of 60% in 10 patients with SDS following HSCT when transplanted before transformation to MDS or MDS/AML.[403] Similarly, the European Group for blood and bone marrow transplantation reported a 64.5% overall survival rate with a median follow-up of 1.1 years in 25 patients with SDS following allogeneic HSCT.[404] From these studies, it is clear that patients transplanted for BMF do much better than those transplanted for MDS or AML. Combining these studies, the overall survival rate for patients transplanted for BMF was 86% (18 of 21) compared with 36% (5 of 14) for those transplanted for MDS/AML. Although the number of patients is small, two studies reported excellent results using reduced-intensity conditioning regimens for HSCT in SDS.[405,406]

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH, MIM 250250), also known as *metaphyseal chondrodysplasia, McKusick type,* is an AR chondrodysplasia.[407]

Clinical Manifestations

CHH is characterized by metaphyseal dysostosis, short-limbed dwarfism, and fine, sparse hair that lacks the central pigment core. Clinical manifestations are highly heterogeneous and vary between and within families. Other skeletal findings include chest deformity, varus lower limbs, lordosis, and scoliosis. Gastrointestinal problems include Hirschsprung disease and other physical anomalies. The disease is more frequent in the Amish and Finnish populations because of a founder effect, with a carrier frequency of 1 in 19 among the Pennsylvania Amish (incidence 1.5 in 1000) and 1 in 76 (incidence 1 in 23,000) among Finns.[377] Mild to severe macrocytic anemia and lymphopenia are present in the majority of patients, whereas neutropenia is seen in only about a fourth. In the majority of individuals the anemia is mild and resolves spontaneously during early childhood. In more severe cases, the anemia resembles Diamond-Blackfan anemia (DBA) or may be accompanied by severe combined immunodeficiency. The severity of the anemia inversely correlates with height. Similar severe combined immunodeficiency is associated with more severe and persistent anemia. Immunodeficiency in CHH is variable. More than 30% of patients have significant CD4 and CD8 lymphopenia, abnormal lymphocyte proliferation upon mitogen stimulation, and impaired humoral immunity with efficiencies in IgG and IgA.[408] Immune dysregulation is thought to be the cause of autoimmune diseases in patients with CHH. The frequency of lymphoid malignant diseases, in particular non-Hodgkin lymphoma, and of basal cell carcinoma is increased about 7-fold. Extended follow-up of persons with CHH revealed that approximately 11% develop malignant disease in adolescence and as young adults. The prognosis of these patients after development of malignant disease is poor.[130,409,410]

Differential Diagnosis

Excluding DBA from the differential diagnosis might be difficult in some cases. Thrombocytosis, increased erythropoietin levels, and increased levels of red cell adenosine deaminase (ADA), characteristic of DBA (see later), may be present in some patients with CHH. Metaphyseal dysplasia has not been reported in patients with DBA. Mutation analysis may be necessary to consolidate the diagnosis.

Milder forms of *Schimke immunoosseous skeletal dysplasia* (MIM 242900) may be difficult to distinguish from CHH. Schimke immunoosseous skeletal dysplasia is characterized by disproportionate short stature, nephropathy, and T-cell deficiency. The disease is an AR disorder caused by mutations in *SMARCAL1*.

Combined immunodeficiency syndromes, in contrast to CHH, are not associated with skeletal abnormalities. *Omenn syndrome* includes short stature and hematologic and immunologic changes; however, Omenn syndrome (MIM 603554) caused by *RAG1* or *RAG2* mutations is more severe and includes ichthyosiform skin.

Congenital neutropenias (see later) caused by mutations in *ELANE*, *HAX1*, *GFI1*, or *WAS* are usually not associated with a skeletal phenotype or have additional systemic manifestations that should distinguish them from CHH.

Genetic Characteristics

CHH is an AR disease. Genetic mapping and DNA sequencing identified the gene encoding the RNA component of *RMRP*, a 265-nucleotide, noncoding RNA gene on 9p21-p12.[378] Mutations responsible for CHH are predominantly found in the transcribed and promoter regions of the *RMRP* gene.[411] The most frequently found mutation is the A70G transversion, which is the major mutation in Finnish and Amish CHH patients. Other mutations include insertional mutations and duplications between the TATA box and the transcription start site that silence transcription. No patient homozygous or compound heterozygous for the promoter region duplications or insertions has been identified, suggesting that these mutations may be lethal. *RMRP* mutations have also been found in a variety of other forms of inherited metaphyseal dysplasia that share features with CHH, including metaphyseal dysplasia without hypotrichosis (MIM 250460), anauxetic dysplasia (MIM 607095), and kyphomelic dysplasia (MIM 211350).[410,412,413]

Gene Function

MRPR is the RNA component of the RNP complex RMRP that is involved in several cellular processes, including mtDNA replication, ribosome biogenesis and pre-rRNA processing, and mRNA degradation of cyclin B2 (*CLB2*), thereby regulating cell cycle progression.[413] MRPR has been described to complex with TERC and possibly is involved in siRNA synthesis; however, these data need further confirmation.[414] Which of these pathways is responsible for BMF is unclear; however, differences and similarities to other ribosomal diseases suggest that the defects in ribosome biogenesis might be responsible for the anemia and that degradation of CLB2 contributes to the increased development of lymphoid tumors. Genotype-phenotype correlation studies suggest a strong correlation between the decrease in rRNA cleavage during ribosomal assembly and the degree of bone dysplasia, whereas reduced mRNA cleavage and cell cycle impairment correlate with the presence of hair hypoplasia, immunodeficiency, hematologic abnormalities, and cancer risk.[412] The clinical manifestations may also be the result of failure of translation of a number of normal genes, as seems to be the case in DBA (see below).

Clinical Management

Skeletal dysplasias might require corrective osteotomies later in childhood or adolescence. Low bone density may complicate orthopedic surgery. Severe anemia requiring transfusion is seen rarely in CHH (6%) and portends a poor prognosis. Transfusions and glucocorticoid may improve the anemia. However, possible benefits of the treatment should be carefully weighed against the potential side effects in a condition associated with immune deficiency and short stature. Although many of the patients outgrow their anemia, in some cases the anemia is severe and persistent, as in patients with DBA.[409] With symptoms of varicella infection, immediate antiviral treatment must be considered to prevent complications. Prophylactic antibiotic therapy in patients with recurrent infections or immunoglobulin replacement therapy if immunoglobulin levels are low may be considered. In patients with severe combined immunodeficiency, significant autoimmune complications, or malignant disease, HSCT with or without myeloablation has been shown to provide long-term immune reconstitution and resolution of autoimmune disease; growth failure remained unaffected, however.[415,416] Thus HSCT should be considered in CHH patients with severe immunodeficiency and/or autoimmunity before the development of severe infections, major organ damage, or malignant disease affects HSCT outcome.

Pearson Syndrome

Pearson marrow-pancreas syndrome (PS, MIM 557000) is a refractory sideroblastic anemia characterized by vacuolization of bone marrow precursors as a result of deletion of mtDNA (Figs. 7-16 and 7-17). Pancreatic dysfunction is frequent but not mandatory for the diagnosis of PS.

Clinical Manifestations

PS is a multisystem disorder that usually becomes evident in early infancy.[374,417] Pancytopenia is frequently associated with dysfunction of the exocrine pancreas, hepatic failure, and renal tubulopathy, which may lead to lactic

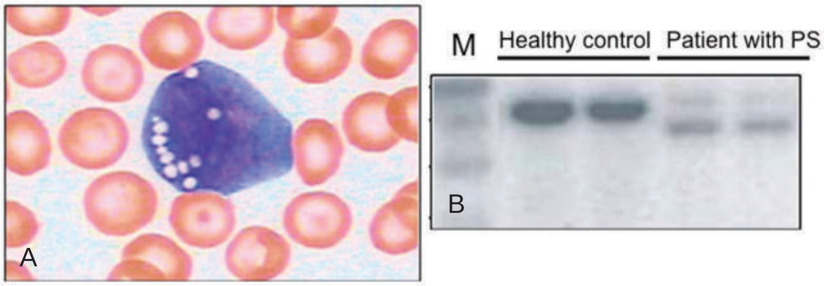

Figure 7-16 Characteristics in Pearson syndrome. A, Myeloid bone marrow precursor cell exhibiting prominent cytoplasmatic vacuolization. B, Southern blot analysis of mitochondrial DNA of a Pearson syndrome patient and a healthy control. The 16.6-kb wild-type mtDNA of the healthy control (lanes 2 and 3) is shown in comparison with the mitochondrial DNA of the patient carrying the 4503-bp deletion (lanes 4 and 5) in approximately 70% of the mitochondrial DNA molecules as quantified densitometrically. *(From Giese A, Kirschner-Schwabe R, Blumchen K, et al: Prenatal manifestation of pancytopenia in Pearson marrow-pancreas syndrome caused by a mitochondrial DNA deletion.* Am J Med Genet *143A:285–288, 2007, Figure 1A and D).*

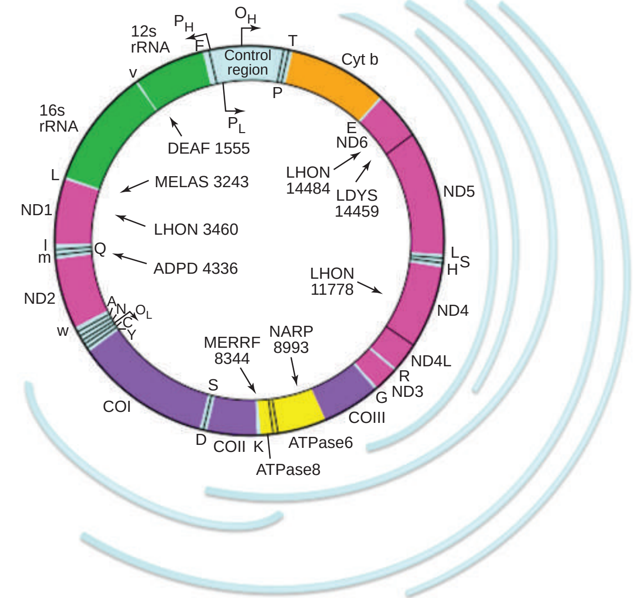

Figure 7-17 Schematic diagram of mitochondrial DNA, indicating an example of the type of deletion found in Pearson syndrome and Kearns-Sayre syndrome. Pink complex 1 genes (nicotinamide adenine dinucleotide dehydrogenase); orange complex III genes (ubiquinol: cytochrome c oxidoreductase); green ribosomal RNA genes; light blue transfer RNA genes; single letters inside are abbreviations of the 22 tRNAs; purple complex IV genes (cytochrome c oxidase); yellow complex V genes (ATP synthase); blue arches indicate the mitochondrial DNA deletions identified in patients with Pearson syndrome and Kearns-Sayre syndrome. *(Modified from* mitomap.org.*)*

acidosis. Vacuolization of hematopoietic precursor cells is characteristic (see Fig. 7-16). Most PS patients die before the age of 3 years. The major cause of death is metabolic acidosis, followed by liver and renal failure. The few surviving children showed hematologic improvement, but typical features of Kearns-Sayre syndrome (MIM 530000) eventually developed.

The male-to-female ratio of PS is 0.7 : 1. Patients from all racial and most ethnic groups have been reported.

Physical anomalies in patients with PS are rare. Approximately a third of patients have exocrine pancreatic insufficiency, and insulin-dependent diabetes develops frequently. Anemia (usually macrocytic) is present in the majority of patients in whom PS is diagnosed before the age of 6 months. Half of patients have neutropenia and thrombocytopenia. Vacuolated myeloid or erythroid precursors, often with decreased erythroblasts, and ringed sideroblasts are present in almost all patients (see Fig. 7-16).

Differential Diagnosis

Vacuolization of the hematopoietic precursor, fibrosis of the pancreas rather than fatty replacement, and the lack of skeletal anomalies distinguishes PS from SDS. PS has to be differentiated from other refractory anemias in children, in particular DBA (see later). Similar to DBA, PS may present with macrocytic anemia, increased fetal hemoglobin, and even an elevated erythrocyte ADA level. However, precursor vacuolization and sideroblasts are characteristic for PS and are not seen in DBA. Mitochondrial enzyme defects and mtDNA deletions usually establish the diagnosis.

Genetic Characteristics

PS is maternally inherited and follows a mitochondrial inheritance pattern (Box 7-14). PS is caused by deletions or duplications of mtDNA.[375,376,418,419] The size of the deletion varies from 2.7 to 7.767 kb[418-420] (see Fig. 7-17). The respiratory enzymes involved in the deletions are relevant to oxidative phosphorylation, and alterations include reduced nicotinamide adenine dinucleotide, cytochrome oxidase, adenosine triphosphatase, tRNA, and rRNA.

The severity of the clinical manifestations and the rate of disease progression are variable. The expression of disease phenotype does not depend on the size of the mtDNA deletion but rather correlates with the ratio of mutated to wild-type mtDNA (heteroplasmy) and with the tissue distribution of mutated mtDNA molecules.[420,421]

Clinical Management

Treatment is mainly symptomatic, with red cell transfusions, alkalizing medications, reduction of further oxidative stress, and carbohydrate restriction. Erythropoietin and G-CSF have been used for the treatment of BMF. The development of leukemia has been reported in one case after HSCT and aggressive immune suppression.[423] The major cause of death is metabolic acidosis, followed by renal and liver failure. The projected median survival time is 4 years, with a plateau rate of 36% at age 10 years. Interestingly, in two patients who received an unrelated HSCT for progressive pancytopenia, there was resolution not only of hematologic complications but also of metabolic acidosis and liver anomalies,[423,424] suggesting that HSCT might be a feasible option in management of PS in the early stages of the disease, before significant organ and tissue damage appear.

Genetic counseling is complicated by the unique genetic features of mtDNA that distinguish it from mendelian disorders, including maternal inheritance, heteroplasmy,

Box 7-14 **Mitochondrial DNA Disorders**

Mitochondria are under genetic control of the mitochondrial and nuclear genomes. Defects in either genome result in mitochondrial disorders. The mitochondrial genome is 16.6 kb in size and encodes 13 enzymes of the respiratory chain, as well as 24 RNA molecules needed for intramitochondrial protein synthesis. Within a cell the mitochondrial genome is present in multiple copies. In healthy individuals, all copies are identical (homoplasmy), whereas in patients with genetic defects of the mitochondrial genome, a mutation can be present in all copies (homoplasmic mutation) or only in some copies (heteroplasmic mutation). Mitochondrial DNA (mtDNA) is usually maternally inherited. For heteroplasmic disorders such as Pearson syndrome, the outcome of a specific pregnancy is difficult to predict, mainly because of considerable variation in the mutated DNA inherited by the offspring and because many of the clinical features correlate with the ratio of mutated to wild-type mtDNA.[417,422]

the threshold effect, the mitochondrial bottleneck, tissue variation, and selection (see Box 7-14).[417,422,425]

Familial Bone Marrow Dysfunction

A large group of patients with BMF do not fit any of the classifications described. If more than one family member is affected, in the absence of environmental exposure explaining BMF, these individuals are classified as having familial BMF, not otherwise specified.

Familial BMF therefore represents a heterogeneous group of individuals and families. In many, BMF is found in various family members and may include aplastic anemia, MDS, leukemia, and immunodeficiency. The inheritance pattern may suggest dominant, recessive, or X-linked disease. In others, the condition may be manifested as sporadic BMF but with associated physical anomalies suggesting an IBMFS not characteristic of FA or any other known IBMFS.

Pathogenesis

A significant number of individuals or families in whom familial BMF is diagnosed most likely have disease caused by one of the major IBMFSs discussed earlier. However, because of variable disease penetrance and expressivity, a possible atypical manifestation, failure to identify the pathogenic mutation, and unawareness of the responsible physician, the correct diagnosis has not been made. For example, BMF secondary to *TERC* or *TERT* gene mutations is certainly underdiagnosed because affected individuals often lack the mucocutaneous features characteristic of classic DC (see earlier). In others, a syndrome specific for particular clinical findings might have been diagnosed, but association with one of the major forms of BMF has not yet been made. Examples from the past are the VATERL syndrome in individuals with vertebral defects, anal atresia, tracheoesophageal fistula, renal defects, and radial limb defects, some of whom turned out to have FA (see the section on FA); HHS, which turned out to be a severe form of DC (see the section on DC); or Kearns-Sayre syndrome, which includes patients with PS who outgrew their BMF (see the section on PS). A small proportion of patients might have an IBMFS resulting from causes that are exceedingly rare and therefore have been missed (see Table 7-1), or the BMF may be due to a mutation in a gene that is not usually associated with BMF. For example, specific mutations in *NBS1*, the gene mutated in Nijmegen breakage syndrome, may manifest as an FA-like phenotype including pancytopenia and a positive DEB or MMC test (also see the section on FA). Finally, a proportion of individuals with familial BMF are presumed to have disease caused by mutations in genes that have not yet been identified. With the availability of whole-genome next-generation sequencing, a number of new and “old genes” will be identified to be associated with the development of BMF.[426,427] One of the challenges will be to determine their significance in the pathogenesis of BMF.

Clinical Management

The overall prognosis in patients with familial BMF is generally less favorable than that in patients with nonfamilial (acquired) BMF. A DEB or MMC test to rule out FA (see the section on FA) and telomere measurements to rule out DC (see the section on DC) are the minimal diagnostic evaluations that should be performed early in the investigation of individuals with familial BMF. *MPL* or *RUNX1* mutation analysis might be considered in patients with a history of thrombocytopenia after birth. Whether *MPL* or *RUNX1* gene testing should be performed in all children presenting with familial or sporadic aplastic anemia is controversial.[428] Cytogenetic investigations should be performed in all patients with aplastic anemia and might reveal constitutional or acquired anomalies that pinpoint or are characteristic of an underlying IBMFS.[429,430] Treatment and supportive care, in general, are the same as those described earlier for FA, DC, or acquired aplastic anemia. Antithymocyte globulin, cyclosporine, androgens, and hematopoietic growth factors have been used with variable success. HSCT from an HLA-matched sibling donor has to be considered carefully because the potential donor may have the same genetic lesion even in the absence of disease. Failure of engraftment has been reported in individuals with familial BMF receiving a transplant from an apparently healthy sibling donor, and development of donor cell–derived malignant disease (MDS/AML) has also been reported in these patients.[284,431] In addition, HSCT may be associated with an unexpected toxicity in patients with familial BMF because the underlying genetic defect may render them hypersensitive to radiotherapy or other agents used for HSCT.

INHERITED BONE MARROW FAILURE SYNDROMES ASSOCIATED WITH ISOLATED CYTOPENIAS

Diamond-Blackfan Anemia

Diamond-Blackfan anemia (DBA, MIM 105650), also known as *congenital erythroid hypoplastic anemia*, is an IBMFS that is usually diagnosed in early infancy (Box 7-15). The disease is named after Louis K. Diamond and Kenneth D. Blackfan, two pediatric hematologists in Boston who first recognized the disease as a distinct clinical entity.[432] DBA is genetically and phenotypically heterogeneous.

Clinical Manifestations

Clinically, DBA is characterized by failure of red cell production and variable congenital anomalies. DBA is a rare disease, with a frequency of 2 to 7 per million

Box 7-15 **Diamond-Blackfan Anemia**

Diamond-Blackfan anemia is a pure red cell aplasia that is usually recognized in early infancy. Diamond-Blackfan anemia is associated with a reduction in or an absence of erythroid precursors in bone marrow, variable congenital anomalies, and a predisposition to malignant disease. Diamond-Blackfan anemia red cells characteristically have increased adenosine deaminase activity.

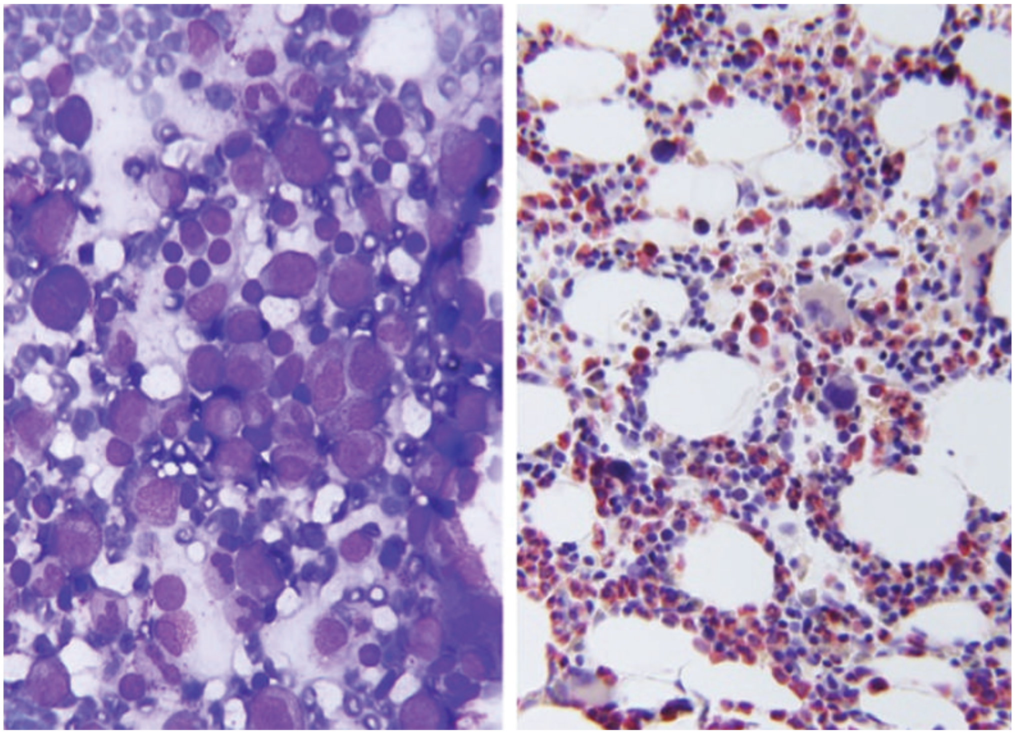

Figure 7-18 Bone marrow aspirate and biopsy obtained from a patient with Diamond-Blackfan anemia. May-Grünwald-Giemsa staining of the aspirate and Leder staining of the biopsy specimen.

live births, and has no ethnic or gender predilection.[433] Much of our knowledge of the disease has been gained from patient registries in North America,[434,435] England,[433,436] Italy,[437,438] France,[439] and the Czech Republic.[440] Classically, patients with DBA present in early childhood with profound macrocytic or normocytic anemia, reticulocytopenia, and a reduction or an absence of erythroid precursors in bone marrow (Fig. 7-18). In more than 90% of patients with DBA the diagnosis is made before the age of 1 year, but in rare cases severe anemia may develop in utero (nonimmune hydrops fetalis) or later in life. The median age at diagnosis is 8 weeks of age.

Congenital Abnormalities

In about 50% of patients DBA is associated with physical anomalies and growth retardation. In some patients a physical anomaly is the only clinical manifestation of DBA. Table 7-8 summarizes the prevalence and range of congenital abnormalities found in patients with DBA. Midline craniofacial defects (e.g., cleft palate), renal anomalies, cardiac malformations, and thumb anomalies (e.g., triphalangeal thumbs) are common.

Short Stature. Although short stature is an integral feature of DBA and is frequently seen in association with other congenital anomalies,[433,441] final height is strongly influenced by glucocorticoid therapy, iron overload, and chronic anemia. Intrauterine growth retardation has been documented in about 20% of individuals with DBA, and characteristically there is an absence of catch-up growth after birth.

Hematologic Abnormalities

Anemia, macrocytosis, reticulocytopenia, and absent or decreased numbers of erythroid progenitor cells in bone marrow are the major diagnostic criteria for DBA. The erythroid marrow may be cellular, albeit with a "leftward shift" toward immature erythroblasts. In 13% to 20% of individuals, anemia may be present at birth.[433,437] Macrocytosis is evident in the majority of cases; however, it may be masked by iron deficiency or thalassemia trait. Increased hemoglobin F levels and persistent "i" antigen are additional features of stress hematopoiesis frequently seen in patients with DBA.[433] Elevated levels of erythrocyte ADA, a critical enzyme in the purine salvage pathway, are characteristic of DBA erythropoiesis and may be found in 80% to 89% of patients.[442,443] Whether macrocytosis, increased fetal hemoglobin, and elevated erythrocyte ADA are integral features of DBA hematopoiesis or rather reflections of stress hematopoiesis remains to be determined. Macrocytosis, increased fetal hemoglobin, persistent "i" antigen, and elevated red cell ADA may be masked in transfusion-dependent patients. In some individuals, macrocytosis or increased red cell ADA levels are the only manifestations of DBA. Parents or siblings of an affected child who have increased red cell ADA levels are likely to be carriers of the pathogenic mutation even in the absence of classic disease (nonclassic DBA). In some individuals with DBA the anemia is transient; however, the macrocytosis and elevated red cell ADA levels often persist. Spontaneous remission of anemia in DBA patients has been reported even after years of steroid or transfusion dependence (also see later). Platelet counts are

usually normal or mildly increased, although platelet counts greater than $1 \times 10^6/\mu L$ and decreased platelet counts have also been reported.[433] White blood cell counts are generally normal but in some cases decrease with age. In rare cases DBA progresses to the full clinical picture of severe aplastic anemia.[435]

Bone marrow examination of children with DBA usually shows normal cellularity, myeloid cells, and megakaryocytes, whereas the bone marrow of adult patients with DBA is often hypocellular (MB personal observation). Lymphocyte counts are often increased. A paucity of erythroid progenitor cells is characteristic. Dyserythropoietic morphology, including ringed sideroblasts, has been reported. Increased iron deposition is evident in patients who have received multiple red cell transfusions. Serum levels of erythropoietin are elevated, and ferrokinetic studies show a delay in plasma iron clearance and low red cell utilization. The slightly shortened autologous red cell survival times and low haptoglobin levels suggest mild hemolysis.[444]

Bone marrow progenitor–derived colony assays show a severe maturation defect in DBA erythroid precursors, whereas other blood cell lineages are unaffected or only moderately impaired.[445] Erythroid colony size and maturation, as well as colony numbers, are impaired. The defect is intrinsic to the erythroid progenitor cell[445] and is partially corrected by interleuklin-3 (IL-3) and stem cell factor[446-448] but not by erythropoietin.[445] The rate of apoptosis of erythroid progenitor cells in cultures from patients with DBA is increased and accentuated after erythropoietin deprivation.[449] More detailed culture analysis pinpoints the defect to the erythropoietin-dependent phase of expansion and differentiation of erythroid progenitors with no significant defect in the preceding erythropoietin-independent stages.[450] Mutations in *RPS19* were shown to be associated with a decrease in proliferation of progenitor cells but normal terminal erythroid differentiation, whereas mutations in *RPL11* were shown to be associated with a decrease in progenitor cell proliferation and a delayed erythroid differentiation with a marked increase in apoptosis.[451] Glucocorticoid treatment increases the erythropoietin sensitivity of both normal and DBA erythroid progenitors, but DBA erythropoietic differentiation and maturation remain suboptimal.[450]

Diagnosis

Table 7-9 summarizes the diagnostic and major and minor supporting criteria. Patients with “classic DBA” have all of the major diagnostic criteria.[452] Patients with “nonclassic DBA” have at least three of the diagnostic criteria features plus one major or two minor supporting features; two diagnostic features and two major or three minor supporting features; or two major supporting features.

Predisposition to Malignant Disease

Patients with DBA have a predisposition to malignant disease with a reported frequency of 1.9% to 6.6%.[435,439] AML (AML/MDS) is the most frequently reported

TABLE 7-9 Diagnostic Criteria for Patients with Diamond-Blackfan Anemia[452]

	SUPPORTING CRITERIA	
Diagnostic Criteria	**Major Criteria**	**Minor Criteria**
Age younger than 1 year	Pathogenic mutations*	Elevated red cell adenosine deaminase
Macrocytic anemia	Positive family histroy	Congenital anomalies of Diamond-Blackfan Anemia
Reticulocytopenia		Elevated fetal hemoglobin
Paucity of bone marrow erythroid precursors		No evidence for other inherited bone marrow failure syndromes

*See Table 7-10.

malignant disease, followed by osteosarcoma.[28,453] In a recent report from the Diamond-Blackfan Anemia Registry of North America, only 6 out of 608 DBA patients developed AML or MDS. Among three of the MDS/AML patients tested, none had a ribosomal gene mutation, raising the possibly that at least some of the patients reported to transform from DBA to MDS/AML might have a different disease pathogenesis.[454] Patients who develop osteosarcoma frequently have a history of growth hormone therapy. Other reported malignant diseases include hepatocellular carcinoma, gastric carcinoma, fibrous histiocytoma, vaginal melanoma, Hodgkin and non-Hodgkin lymphoma, breast cancer, and ALL. The medium age at diagnosis of malignant disease was 15 years (range, 1 to 43 years), as opposed to 68 years in a non-DBA control group. The relative risk of all cancers (excluding MDS) in DBA was increased significantly (5.4-fold), with a cumulative incidence of 22% by age 46 years.[453] A phenotype-genotype correlation for the development of cancer is not yet available.

Differential Diagnosis

Clinically, DBA has to be distinguished from other IBMFSs such FA, DC, SDS, CHH, and PS. Clinical manifestations, associated physical abnormalities, family history, a negative chromosome fragility test (DEB or MMC test), and normal telomere length measurements are helpful in strengthening the diagnosis of DBA. Distinguishing DBA from CHH may be difficult. The anemia in CHH is usually less severe but may be similar to that seen in patients with DBA.[409] In the absence of distinguishing features, only identification of the responsible mutation may differentiate between the two conditions. Interestingly, both the RMRP responsible for CHH and the ribosomal proteins responsible for DBA participate in ribosome biogenesis, which may explain the similarities in hematologic manifestations. In patients with PS, BMF is classically accompanied by characteristic vacuolization of hematopoietic precursor cells.[374] Finally, congenital anemia, neutropenia, and trilineage dysplasia caused by *GATA1* gene mutations causes a congenital macrocytic anemia; however, it is not associated with congenital anomalies. Indeed, in some cases *GATA1* gene mutations produce a phenotype that is indistinguishable from ribosomal gene mutations caused by DBA (see below and Table 7-8)(Box 7-16).

DBA has to be distinguished from acquired forms of anemia, including transient erythroblastopenia of childhood (TEC; see later and Chapter 6); viral infections, including infection with human immunodeficiency virus and infectious mononucleosis; drug-related anemia; anemia caused by exposure to toxic chemicals; severe renal failure; and anemia after an ABO-incompatible transplant (for a comprehensive list of possible causes of anemia in childhood, see Vlachos and associates[452]).

Genetic Characteristics

DBA occurs in both familial and sporadic forms. Gene mutations identified in patients with DBA are summarized in Table 7-10. Approximately 70% of patients have identifiable mutations in one of several ribosomal protein genes.[455] Genes encoding proteins of both the small (RPS) and large (RPL) ribosomal subunits may be affected. Large deletions of ribosomal genes account for about 20% to 26% of patients with DBA and may be overlooked when gene sequencing is the only method used for mutation detection.[456,457] In approximately two thirds of cases the mutation occurs de novo; in about one third the mutation is inherited and typically follows AD inheritance.[458] Rare cases of AR inheritance have been reported.[436,459,460] It remains to be determined whether these cases are indeed due to biallelic mutations or are caused by incomplete penetrance of an otherwise dominant mutation mimicking sporadic or AR disease.[435,436] Finally, in two families *GATA1* mutations were identified to be the cause of congenital red cell aplasia with an X-linked inheritance pattern affecting only male family members.[461]

Diamond-Blackfan Anemia Genes and Their Functions

Following from the observation that a DBA patient had an X;19 chromosomal translocation,[462] the first gene to be identified as being mutated in DBA was the *RPS19* gene at 19q13.2.[463] Subsequently, it was established that a fourth of DBA patients harbor a mutation in *RPS19*,[464,465] which encodes the small subunit ribosomal protein 19. The mutations are always heterozygous and include

Box 7-16 Ribosomes

Ribosomes are intracellular organelles about 200 Å in diameter that consist of RNA (ribosomal RNA [rRNA]) and protein (ribosomal proteins). In all organisms, ribosomes are the site of protein synthesis and translation of messenger RNA molecules into continuous chains of amino acids (polypeptides or proteins). The ribosome is a ribozyme, which means that it is the rRNA that catalyzes decoding of the message and the formation of peptide bonds. Ribosomal proteins, on the other hand, are important for maturation of rRNA precursors and ensure their correct structure in the ribosome.

missense, nonsense, frameshift, and splice-site mutations, as well as small and large gene deletions and chromosomal translocations with the breakpoint in the *RPS19* gene. Whereas the nonsense and frameshift mutations are spread evenly throughout the coding region, the missense mutations are clustered. RPS19 haploinsufficiency is thought to be responsible for disease.[466] Analysis of the crystal structure of RPS19 from *Pyrococcus abyssi* suggests that missense mutations in DBA primarily affect the capacity of the protein to be incorporated into preribosomes, thus blocking maturation of pre-40S particles.[467]

Since then pathogenic mutations have been found in other ribosomal proteins from either the large or small subunits. Ribosomal proteins are an integral component of ribosomes (Box 7-17). Although ribosomal proteins do not participate in the protein synthesis activity of the ribosome, they are important for maintaining the structure and conformation of the ribosome during biosynthesis and for its function in translation (see Boxes 7-16 and 7-17 and Figs. 7-19 and 7-20). The finding that the great majority of mutations causing DBA affect ribosomal proteins led to the concept that for most patients, DBA is a disorder of ribosome biogenesis or a ribosomopathy.

The spectrum of RP gene mutations in DBA range from single amino acid substitutions to small deletions or insertions to nonsense mutations, splicing mutations, and large deletions. This pattern suggests that loss of function leading to haploinsufficiency is the mechanism of pathogenesis for all the RP loci involved. Mutations in ribosomal genes identified in patients with DBA, along with their functional consequences and phenotype, are catalogued in the DBA Mutation Database (www.dbagenes.unito.it).[458,470]

The only mutations leading to DBA not in an RP gene have been found in the *GATA1* gene.[461] The GATA1 patients diagnosed with DBA present with an overlapping phenotype that includes macrocytic anemia, increased fetal hemoglobin, and a responsiveness to glucocorticoids (Fig. 7-21). In contrast to DBA caused by ribosomal protein mutations, individuals with *GATA1* mutations lack increased erythrocyte ADA and congenital anomalies.[461,471] The *GATA1* mutations associated with a DBA-like phenotype are located at the end of exon 2 and favor the production of a short form of GATA1 (GATA1s) that lacks amino acids 1 to 83.[472] This region, the NH_2-terminal activation domain (NAD), binds the retinoblastoma tumor suppressor protein and may regulate the capacity of GATA1 to control cell survival or proliferation. Whether a link exists between RP haploinsufficiency

Box 7-17 **Ribosome Biogenesis and Preribosomal RNA Processing**

Ribosome biogenesis is the new production of ribosomes. In eukaryotes, ribosome biogenesis takes place in the nucleolus, a specialized compartment within the nucleus. Ribosome biogenesis is a complicated, highly regulated process that begins with the synthesis of large preribosomal RNA. Structural rearrangements and cleavage occur as the ribosomal proteins are incorporated to ultimately give rise to mature ribosome subunits. Final maturation of the ribosome subunits takes place in the cytoplasm before they become assembled to form the mature ribosome (see Figs. 7-19 and 7-20).[468,469]

Figure 7-19 Diagram of the six major steps in ribosome biogenesis. 1. Pol I transcription: The process starts with transcription of the multiple copies of the genes for rRNA (rDNA) to form the large preribosomal RNA primary transcript. 2. Preribosomal RNA modification: The preribosomal RNA is methylated and pseudouridylated under the guidance of the small nucleolar RNAs. Nonribosomal proteins *(open circles)* and small nucleolar RNAs *(open rectangles)* associate with the nascent transcript. 3. Preribosomal RNA processing: The preribosomal RNA undergoes a series of cleavages, ultimately resulting in 18S, 5.8S, and 28S ribosomal RNAs. 5S ribosomal RNA, a component of the 60S subunit, is added to the maturing complex. The complex is split into the two precursor particles for the small (40S) and large (60S) ribosomal subunits. 4. Preribosome assembly: Ribosomal proteins *(black circles)* are added to the precursor complexes at various stages of assembly. 5. Structural reorganization and transport: The nearly mature subunits are exported to the cytoplasm through the nuclear pore complexes with the aid of adaptor proteins. 6. Late maturation: The small and large subunits are eventually incorporated into ribosomes in the cytoplasm. Dyskeratosis congenita affects ribosome biogenesis at the preribosomal RNA modification step (step 2); Diamond-Blackfan anemia and cartilage-hair hypoplasia affect ribosome biogenesis at the preribosomal RNA processing step (step 3).

Figure 7-20 Preribosomal RNA processing. The 18S, 5.8S, and 28S ribosomal RNAs are transcribed as a single precursor (45S), which is subsequently processed into mature species by a complex series of cleavage and modification reactions. In addition to the mature ribosomal RNA species, the primary precursor (47S) contains two external transcriber spacers at its 5′ and 3′-ends (5′-ETS and 3′-ETS, respectively), as well two internal transcriber spacers (ITS1 and ITS2). After synthesis of the primary preribosomal RNA molecule is completed, the transcriber spacer sequences are removed by a series of endonucleolytic cleavage and exonucleolytic degradation steps. Two alternative preribosomal RNA processing pathways, A and B, have been described in HeLa cells. *(From Hadjiolova KV, Nicoloso M, Mazan S, et al: Alternative pre-rRNA processing pathways in human cells and their alteration by cycloheximide inhibition of protein synthesis.* Eur J Biochem *212:211–215, 1993; Mullineux ST, Lafontaine DL: Mapping the cleavage sites on mammalian pre-rRNAs: where do we stand?* Biochimie *94:1521–1532, 2012.)*

and *GATA1* expression remains to be determined.[473] Recent studies of Sankaran and colleagues[461] suggest that failure of GATA1 translation (and presumably the translation of other genes) may account for the variable manifestations of DBA. This highlights the importance of correlating molecular and clinical diagnoses in the management of rare diseases as more genetic causes are described.[473]

Genotype-Phenotype Correlation

No striking correlation has been found between the mutated gene and the severity of the BMF in DBA. Disease severity is highly variable among patients with mutations in the same gene and even among affected members of the same family. There is a clear phenotype-genotype correlation, however, in terms of the expression of physical malformations and small stature.[440,455,458,474] Patients with no phonotypical anomalies are most frequently *RPS19* gene mutation carriers or patients with *GATA1* mutations, whereas patients with *RPL5* or *RPL11* mutations more frequently have thumb and congenital heart defects. Indeed, thumb anomalies are not found in patients with *RPS19* gene mutations. Patients with *RPL5* mutations seem to be more frequently affected with craniofacial malformations, while patients with *RPL11* mutations more frequently have hand abnormalities.[440,475-477] Patients with *RPS26* mutations have no thumb anomalies or

craniofacial dysmorphisms; instead they have skeletal abnormalities, including microcephaly, Sprengel deformity, Klippel-Feil syndrome, or rib anomalies.[440]

Molecular Diagnosis of Diamond-Blackfan Anemia

Currently, molecular diagnosis is not routinely performed for DBA, because it is expensive. If deletion detection is included, genetic testing can currently provide a definite diagnosis in about 70% of cases (about 50% to 60% if gene deletion detection is not included).[455] Furthermore, molecular diagnostic testing enables the identification of mutation carriers, facilitates prenatal diagnosis for an existing pregnancy, and allows preimplantation genetic diagnosis for partners identified as mutation carriers. Anomalies in addition to the ones characteristic for DBA, in particular, mental retardation, are suggestive of a large deletion causing haploinsufficiency for additional genes in the vicinity of the deleted DBA gene.

Diseases Related to Diamond-Blackfan Anemia

Aase Syndrome. Congenital red cell aplasia with a triphalangeal thumb has been described by Aase and Smith as a distinct syndrome.[478] Cleft palate and cardiac anomalies have been associated with this syndrome. Its clinical manifestations have significant overlap with those characteristic of DBA; thus Aase syndrome most likely represents a subset of patients with DBA who have a particular phenotype.

Myelodysplasia with Deletion of Chromosome 5q (5q– Syndrome). Patients with a deletion of the long arm of chromosome 5 (5q– syndrome) have severe macrocytic anemia, elevated platelet counts, erythroid hypoplasia in the bone marrow, and hypolobulated megakarocytes. Delineation of the critical deletion region on chromosome 5q– includes the *RPS14* gene at position 5q33.1 and about 40 additional genes.[479] Reducing RPS14 expression in normal CD34+ cells leads to a gene expression profile similar to that found in bone marrow cells from patients with 5q– MDS and results in selective impairment of erythroid differentiation with only minor effects on megakaryopoiesis or myelopoiesis. Similarly, enforced expression of RPS14 restores the erythroid phenotype in bone marrow cells from patients with 5q– MDS, suggesting that erythroid hypoplasia is caused by *RPS14* haploinsufficiency.[479] In contrast to patients with DBA, the deletion of *RPS14* in patients with 5q– MDS is not inherited but is acquired in early hematopoietic progenitor cells (somatic). Heterozygous loss of the *RPS14* gene leads to activation of p53 in erythroid cells and explains the macrocytic anemia in 5q– MDS. The megakaryocytic and platelet phenotype of 5q– MDS has been attributed to heterozygous deletion of miR145 and miR146a. Murine models have implicated heterozygous loss of *APC*, *EGR1*, *DIAPH1*, and *NPM1* in the pathophysiology of 5q– MDS. These findings indicate that haploinsufficiency or loss of heterozygosity for additional genes affected by the deletion causes the growth advantage of the mutant cells.[480] Interestingly, MDS with 5q– shows a remarkable response to the thalidomide analogue lenalidomide, which is thought to be in part mediated through the inhibition of Cdc25C, resulting in G_2- and M-phase arrest and apoptosis of 5q– cells, in part through the stabilization of HDM2, leading to the degradation of p53 and the restoration of erythropoiesis.[481]

Transient Erythroblastopenia of Childhood. Transient erythroblastopenia of childhood (TEC, MIM 227050) is a rare pure red cell aplasia that occurs most commonly between 6 months and 4 years of age (see Chapter 6).[482] Laboratory findings consist of normocytic normochromic anemia and reticulocytopenia, sometimes associated with thrombocytosis and erythroblastopenia of bone marrow.[482] The course is characterized by complete recovery, usually within 1 to 2 months after diagnosis. No therapy is usually necessary, although some children may require red cell transfusion. The absence of macrocytosis, increased fetal hemoglobin, and increased erythrocyte ADA levels in individuals with TEC are used to distinguish TEC from DBA.[482] In addition, congenital abnormalities are not present in patients with TEC. The etiology of TEC is not entirely clear, but is thought to be postinfectious and possibly autoimmune mediated. The majority of TEC cases are sporadic and acquired, but there are a few reports of familial TEC. Linkage analysis suggested allelism for TEC at the *RPS19* gene locus; however, no mutations in the *RPS19* coding region were identified.[483]

Animal Models

Mice haploinsufficient for *Rps19*, due to heterozygosity for a deletion mutant, are asymptomatic and have normal levels of Rps19 mRNA and protein, indicating that mice can compensate for the gene deficiency but humans cannot.[484,485] Missense mutations in Rps19, isolated in an experiment selecting for a dark skin phenotype, had a mild macrocytic anemia, which was reversed, as was the dark skin, in a $p53^{-/-}$ background.[486] Induced haploinsufficiency for Rps6 produced a mild macrocytic anemia with granulocytopenia, thrombocytosis, lymphopenia, and elevated eADA levels. The anemia responded to lenalidomide treatment.[487] The most faithful model of DBA in mice was produced by making mice transgenic for Rps19 shRNA, whose presence decreases the level of Rps19 mRNA.[488] These mice showed macrocytic anemia with leukocytopenia and variable platelet count. They also had ribosome profile abnormalities and increased apoptosis in hematopoietic progenitors. The phenotype could be rescued by either expression of Rps19 or depletion of p53. Treatment of these mice with leucine produced beneficial effects, with increases in hemoglobin concentration and erythrocyte number.[489]

A number of *Drosophila* mutants called minutes are due to haploinsufficiency for various ribosomal proteins and share some features with DBA.[307] Affected flies have developmental delay and small size. Phenotypes in DBA and *Drosophila* minutes affect cells and tissues with a high rate of protein synthesis (bone marrow cells in humans and sensory bristles in flies). In both species the phenotype is only produced by haploinsufficiency of certain ribosomal proteins but not all. This may indicate that ribosomal protein expression, which varies between different proteins, needs to fall below a critical level for the phenotypes to develop.

In zebrafish several ribosomal protein knockdowns, including those for RPS19 and RPL11, have produced developmental, morphologic, and hematopoietic defects some of which are similar to those seen in DBA,[490-493] though it is difficult to accurately produce haploinsufficiency in this organism. Concomitant knockdown of p53 often rescued the phenotypes; in one case developmental, but not hematopoietic, defects responded to p53 deficiency.[494]

Mechanism of Disease Pathogenesis in Diamond-Blackfan Anemia

The mechanism whereby mutations in *RPS19* or the other ribosomal proteins cause specific defects in red cell maturation is not fully understood and is the focus of current research in the field. The fact that different ribosomal proteins from both subunits can be mutated in DBA suggests that impaired ribosome biogenesis is important in pathogenesis. But why should this process, which is important in all cells, specifically affect erythropoiesis? One prevailing hypothesis amongst investigators is that in a cell that is synthesizing ribosomes at a high rate, shortage of a ribosomal protein leads to an excess in the nucleus of other ribosomal proteins that are not incorporated into ribosomes (ribosome stress).[495] These include RPL5 and RPL11, which bind 5S rRNA in the nucleus[496] and can specifically interact with MDM2 and prevent it from ubiquitinating p53. The concentration of p53 not marked for degradation increases and signals a cell cycle arrest and apoptosis (Fig. 7-22, *A* and *B*). There is good evidence for many of the steps in this process. Levels of the tumor suppressor p53 are maintained as part of a feedback loop whereby MDM2 is an E3 ubiquitin ligase that leads to p53 degradation while it is itself

Figure 7-22 Current model for how RP haploinsufficiency causes Diamond-Blackfan anemia. **A,** Normal erythroblasts produce large numbers of ribosomes for protein synthesis. Levels of p53 remain low via a feedback loop whereby MDM2, a transcriptional p53 target, ubiquitinates p53 to promote its degradation by proteasomes. **B,** Haploinsufficiency for specific RPs causes accumulation of other RPs, which bind to MDM2, thereby inhibiting its ability to promote p53 degradation. Consequently, p53 accumulates and triggers cell cycle arrest and apoptosis. *(Modified from Weiss MJ, Mason PJ, Bessler M: What's in a name?* J Clin Invest *122:2346–2349, 2012.)*

a transcriptional target of p53.[497-499] MDM2 binds RPL11 and RPL5, and their binding inhibits the action of MDM2 in p53 turnover.[500-502] The mechanism by which RPL11 and RPL5 accumulate under conditions of ribosome stress has not been clearly delineated, but it was recently suggested, with experimental evidence, that under these conditions most ribosomal proteins are degraded in the nucleus but RPL11 and RPL5 mutually interact and protect each other from degradation.[503] The scheme also accounts for the role played by p53 in the response to ribosome stress as demonstrated by increased p53 in cells undergoing ribosome stress and the rescue of DBA-like phenotypes in animal models of DBA by p53 depletion. Unanswered questions remain. Why are some mutations in some ribosomal protein genes frequent causes of DBA but others infrequent causes, and why have some never been found? Why are the two proteins that bind to MDM2 in response to ribosome stress, RPL5 and RPL11, encoded by the most frequently mutated large subunit genes?

An alternative hypothesis is that maturing erythrocytes are producing vast amounts of globin and vast amounts of heme. When ribosome synthesis is faulty, the amount of globin produced decreases but the decrease does not affect the rate of production of heme, which then accumulates and is toxic to the cells. A mouse in which the gene encoding FLVCR, a heme export protein,[504] can be inactivated develops many of the features of DBA, including macrocytic anemia.[505] Further investigation is needed to clarify whether these mechanisms operate in DBA.

Clinical Management

The actuarial survival rate at 40 years of age is 75%.[435] Survival is significantly better for steroid-responsive patients than for transfusion-dependent patients.[433,435,438-440] The major causes of death are treatment related and include infection (in particular, *Pneumocystis jiroveci* pneumonia), complications of iron overload, and complications of HSCT. Other causes of death include evolution to severe aplastic anemia and malignant disease.

Glucocorticoid Therapy. Glucocorticoids and red cell transfusions are the main forms of therapy. Prednisone (or prednisolone) therapy is usually initiated at a dosage of 2 mg/kg/day. For glucocorticoid responders, the prednisone dosage is slowly tapered until the patient is taking an alternate-day dosage that maintains a reasonable hemoglobin level. Many patients remain on low, alternate-day doses of steroids for years. Seventy percent to 80% of patients with DBA are initially steroid responsive, but only 60% to 70% achieve transfusion independence.[452,506] Response to treatment is usually seen within 1 month. The likelihood of response cannot be predicted. The steroid dose is tapered to the lowest dose necessary to maintain transfusion independence. The maintenance dose of steroids is highly variable, with some requiring only minimal doses. The mechanism of glucocorticoid-induced remission is as yet unknown.

Side effects of steroid therapy include growth retardation, increased risk of infection, diabetes mellitus, hypertension, cushingoid features, pathologic fractures, cataracts, avascular osteonecrosis, osteopenia without fracture, pseudotumor cerebri, and, in infants, delay in neuromotor development.[433,452] Steroid therapy is often not recommended in infants younger than 6 months.[452,506] Individuals taking high doses of steroids require *P. jiroveci* prophylaxis. The steroid maintenance dosage should not exceed 0.5 mg/kg/day (or 1 mg/kg every other day) and should be discontinued in the absence of response (for more detailed information, see the consensus document regarding diagnosis and management of DBA[452]).

Transfusion Therapy. Red cell transfusion remains the mainstay of therapy for steroid-resistant disease, as well as for treatment of DBA in early infancy (<6 to 12 months of age). Leukocyte-depleted packed red cells should be given every 3 to 6 weeks to maintain a hemoglobin level of about 8 g/dL.[452] The major complication from transfusions is iron overload. Complications associated with iron overload are the second most common cause of death in patients with DBA.[433,435,438-440] Complications of iron overload include endocrinopathy, diabetes, growth failure, and failure to enter puberty, as well as cardiac failure and liver disease. Serum ferritin is not a reliable indicator of the body's iron load, in particular in patients with DBA. There is evolving evidence for an increased cardiac and liver iron uptake in patients with DBA compared with patients with thalassemia.[507-510] Measurements taken from a liver biopsy specimen are the gold standard for estimating hepatic iron concentration. Noninvasive methods of iron measurement include magnetic susceptometry (superconducting quantum interference device) and magnetic resonance imaging. Iron chelation should begin as soon as patients have increased iron stores (ferritin >1500 mg/dL, hepatic iron >6 to 7 mg/g, which corresponds to a transfusion history of about 170 to 200 mL of packed red blood cells/kg). Subcutaneous infusion of deferoxamine had been the standard chelation therapy in patients with DBA for many years. More recently the oral iron chelator deferasirox, a tridentate, has supplanted deferoxamine as the standard chelation therapy.[511] Deferasirox may be given in combination with deferoxamine.

The oral iron chelator deferiprone, a bidentate chelator available in Europe for quite some time, has become available recently in the United States. Side effects of deferiprone include neutropenia (6%) and agranulocytosis (0.6%). Fatal agranulocytosis has been described in one patient with DBA taking deferiprone in addition to deferoxamine.[512] The use of deferiprone in patients with DBA should therefore be avoided. Iron chelation is contraindicated during pregnancy and should cease when pregnancy is planned or confirmed.[513,514]

Hematopoietic Stem Cell Transplantation. HSCT is curative in patients with DBA and may be considered in transfusion-dependent patients, in particular those who have an HLA-matched sibling donor, patients with DBA progressing to severe aplastic anemia, or patients in whom MDS/AML develops. Data from the DBA registry showed survival rates of 90% in individuals below the age of 9 years and 70% in individuals 9 years and older with transplants from sibling donors. Survival rates for DBA patients receiving a transplant from an alternative donor were less encouraging in the past; with more extensive HLA typing, improved iron chelation, and pretransplant and posttransplant care, the rate was found to be 86%.[515] The survival rate is similar with unrelated marrow and cord blood donors, but a report from the Aplastic Anemia Committee of the Japanese Society of Pediatric Hematology suggests that marrow might be superior to cord blood cells.[516] In a recent report from the Eurocord and the Severe Aplastic Anemia Working Party from the European Group for Blood and Marrow Transplant, following an umbilical cord transplant in 21 patients with DBA, 13 received a related cord and 8 an unrelated cord. Of those who received a related graft all were alive at a median follow-up of 65 months. Of the five patients with DBA who received an unrelated cord, three were alive at a median follow-up of 31 months, suggesting that umbilical cord transplantation is an excellent option for children with hereditary BMF syndromes such as DBA when the donor is an HLA-matched sibling donor.[517] The decision to perform HSCT in patients with DBA is confounded by the possibility of spontaneous remission. HSCT is generally more successful in young patients who have received relatively few transfusions.[435]

Alternative Therapies. Several other therapeutic approaches used over the last 30 years include androgens, erythropoietin, IL-3, stem cell factor, antilymphocyte globulin, cyclosporine, and valproic acid. Although occasional hematologic responses were observed, none of these therapies became a major player in the treatment of DBA. Treatment with metoclopramide, a dopamine antagonist, elicited transfusion independence in a small number of individuals with DBA.[518-520]

Splenectomy was reported in approximately 40 patients, with no beneficial effect noted except in those who had hypersplenism related to transfusions. More than half of the splenectomized patients died, often from infections. Splenectomy is no longer recommended but with vaccination and antibiotic prophylaxis might be reconsidered for specific patients.

More recently, leucine, an amino acid that increases protein synthesis, has been reported to be beneficial for some DBA patients studied in a small series in the Czech Republic.[521] Leucine is a branched-chain amino acid that is a substrate for protein synthesis but also serves as a nutrient that regulates protein metabolism through activation of mTOR.[522] Studies in mouse and zebrafish models of DBA showed that leucine treatment resulted in improvement of anemia and that leucine treatment of RPS19-deficient erythroblasts increased cell proliferation, erythroid differentiation, and mRNA translation in culture.[489,523] Clinical trials employing leucine in the treatment of DBA are currently in progress.

Spontaneous Hematologic Remission. About 20% to 30% of patients experience spontaneous hematologic remission, defined as a stable, physiologically acceptable hemoglobin level maintained for at least 6 months, independent of glucocorticoid treatment, transfusion, or other therapy.[434,435] In the majority of cases hematologic remission occurs within the first or second decade of life in patients who were steroid responsive. The hematologic is often stable. However, relapse of hematologic disease has been observed, in particular during pregnancy or in women using estrogen-based oral contraception.[435] The molecular basis of the hematologic remission is not fully understood. In two patients, one with an *RPS17* gene mutation and one with an *RPL35* gene mutation, somatic mosaicism for copy-number neutral loss of heterozygosity of chromosomes 15q and 3q, respectively, has been identified in peripheral blood cells.[456] This suggests that somatic mitotic recombination occurring in early hematopoietic progenitor cells may be responsible for the normalization of peripheral blood cell counts in these two patients.

Pregnancy in Diamond-Blackfan Patients

Pregnancy in women with DBA is associated with an increased frequency of complications in the mother and child, including preeclampsia, fetal loss, intrauterine death, premature delivery, intrauterine growth retardation, and congenital anomalies.[433,524] It has been suggested that these complications are of vascular-placental origin, and treatment with aspirin has been reported to be beneficial in some cases.[524] Almost half of patients had transient worsening of anemia during pregnancy. The maternal hemoglobin level should be maintained at greater than 9 to 10 g/dL to avoid maternal anemia, which might lead to intrauterine growth retardation, preterm delivery, or fetal distress. Women planning to become pregnant should be evaluated for conditions that might compromise the outcome of pregnancy, including bloodborne infectious diseases, iron overload and related diabetes mellitus, hypothyroidism, and cardiomyopathy. Iron chelation is contraindicated during pregnancy and should cease when pregnancy is planned or confirmed. Deferoxamine is teratogenic in rodents but deferasirox is not; however, neither medication is licensed for use in pregnant women.[452]

Cancer Surveillance and Treatment

In addition to an increased risk for AML, there appears to be an association of osteosarcoma and other malignant diseases with DBA.[453] Bone marrow biopsy plus cytogenetic evaluation is indicated when abnormalities suggestive of MDS or MDS/AML are noted or when the disease progresses to aplastic anemia.[452] In contrast to other IBMFSs routine yearly bone marrow biopsies are not recommended in DBA.[452] Growth hormone therapy is not usually recommended in individuals with DBA and small stature, because of the potential increased risk for osteosarcoma.[453] Whether malignant diseases occurring in patients with DBA differ in their biology and response to treatment from similar diseases occurring in non-DBA individuals remains to be determined. Similarly, levels of toxicity in DBA patients with cancer to certain chemotherapy agents remain to be determined.

Box 7-18 Ineffective Erythropoiesis/Dyserythropoiesis

Ineffective erythropoiesis results when in intact, stimulated bone marrow, red blood cell precursors either fail to mature or die in the bone marrow before delivery to the circulation as erythrocytes. Dyserythropoiesis usually defines a qualitative defect in red cells or red cell precursors, or both. Dyserythropoiesis often leads to ineffective erythropoiesis with intramedullary destruction of red cells and their precursors and often a decreased half-life of circulating red blood cells.

Congenital Dyserythropoietic Anemias

Congenital dyserythropoietic anemias (CDAs) are a group of rare genetic disorders characterized by ineffective erythropoiesis and distinctive morphologic abnormalities in bone marrow erythroblasts.[525] Dyserythropoiesis is the major cause of anemia in patients with CDA, although a shortened half-life of the mature cells in circulation may also contribute to anemia (for the definition of dyserythropoiesis see Box 7-18). CDAs are often not considered to belong to the group of IBMFSs. Nevertheless, CDAs are genetic conditions that affect red blood cell production in bone marrow and lead to anemia associated with an inadequate reticulocytosis.

Four major forms of CDA and several minor subgroups have been identified. The main characteristics of the four major forms of CDA are summarized in Table 7-11 (for review see also Iolascon et al, 2011,[526] and Iolascon et al, 2012[527]). Shared clinical symptoms include anemia of variable degree, intermittent jaundice, hepatomegaly, splenomegaly, cholelithiasis, and iron overload. Additionally, extramedullary hematopoiesis presenting as a paravertebral mass may be observed in all types of CDAs.

Differential Diagnosis

CDA should be considered when the reticulocyte response is suboptimal for the degree of anemia in a patient with erythroid hyperplasia or when there is unexplained hyperbilirubinemia or iron overload. Other congenital anemias and acquired disorders associated with dyserythropoiesis that should be excluded include thalassemia syndromes, hemoglobin C, certain unstable hemoglobins, hereditary sideroblastic anemias, hereditary persistence of fetal hemoglobin, red blood cell membrane defect, vitamin B_{12} or folate deficiency, iron deficiency, alcohol abuse, liver disease, heavy metal poisoning, and MDS.

Clinical Management

Treatment is essentially symptomatic. Prevention of severe tissue damage secondary to iron overload is important. Splenectomy results in hematologic improvement in some patients with CDA type II[528]; transfusion independence was also achieved in the one patient with CDA type IV in whom splenectomy was performed.[529] Splenectomy in CDA does not have a beneficial effect on iron overload. The benefit of splenectomy in other forms of CDA is controversial. Patients with CDA type I show hematologic improvement and a reduction in iron overload in response to recombinant interferon alfa.[530,531] Successful treatment with allogeneic HSCT in combination with intensive iron chelation therapy has been reported in severely affected patients with CDA.[532,533] In contrast to other IBMFSs, CDA is not associated with a significantly increased risk for leukemia or cancer.

Congenital Dyserythropoietic Anemia Type I

Clinical Characteristics. The incidence of CDA type I is about 1 per 100,000 births per year, and more than 150 patients have been described. Consanguinity may be the cause of an increased incidence in some areas such as the Middle East. In most patients the diagnosis is made during childhood and adolescence. Anemia is moderate, with a mild macrocytosis and frequent eliptocytes. Clinical manifestations in newborns include small stature, hepatosplenomegaly, jaundice, pulmonary hypertension, abnormal liver parameters, and, in some cases, transient thrombocytopenia. Red blood cell transfusions are often required for newborns and infants but are only occasionally necessary later in life. Splenomegaly is evident in 80% to 90% of adult patients. Occasionally, severe erythroid hyperplasia may cause skeletal deformities such as frontal bossing or paravertebral tumors secondary to extramedullary hematopoiesis.

Iron overload with increased ferritin levels is frequent even in untransfused patients. Liver cirrhosis, increased skin pigmentation, and endocrine dysfunction as a result of iron overload have been reported in occasional patients.[534,535] The increased iron loading is due to the enhanced absorption of iron that usually accompanies ineffective erythropoiesis. In fact, hepcidin levels are reduced in CDA type I patients.[536]

Congenital abnormalities are associated with some CDA type I cases and include abnormalities of the fingers, toes, and wrists; short stature; pigeon chest deformity; deformity of the hips, vertebral bodies, and ribs; abnormal skin pigmentation; congenital ptosis; and deafness.[537-539]

Laboratory Findings. The anemia in CDA type I is moderate, with hemoglobin levels between 6.6 and 11.6 g/dL. Red cell morphology includes macrocytosis, severe anisopoikilocytosis, and basophilic stippling. Inappropriate suppression of hepcidin, high levels of serum hemojuvelin, and high levels of growth differentiation factor 15 (GDF15) have been described in patients with CDA I and II, probably contributing to secondary hemochromatosis. The role of GDF15 in iron absorption is uncertain. The bone marrow in patients with CDA I shows erythroid hyperplasia with megaloblastic changes. Diagnostic of CDA type I is the finding of internuclear chromatin bridges between nearly completely separated erythroblasts, which is seen in about 0.6% to 2.8% of the early and late polychromatic erythroblasts (Fig. 7-23).[539] Though characteristic of CDA type I, internuclear chromatin bridges may also be found in acquired dyserythropoietic states, such as MDS. The characteristic electron microscopic abnormality in CDA type I is a spongy "Swiss-cheese" appearance of heterochromatin in up to 60% of intermediate and late erythroblasts. Additional findings characteristic of CDA type I are summarized in

TABLE 7-11 Features of Congenital Dyserythropoietic Anemias

Feature	Type I (see Fig. 7-23) MIM #224120	Type II (HEMPAS, see Fig. 7-24) MIM #224100	Type III (see Fig. 7-25) MIM #105600	Type IV MIM #613673
Male/female ratio	1:1	0:9	0:8	
Incidence	<1/100,000/year; founder effect in Switzerland, Israel	<1/100,000/year; most common form; founder effect in Italy	Very rare; founder effect in Sweden, Argentina	Very rare (4 patients reported)
Anemia	Mild to moderate	Moderate	Mild to moderate	Severe hemolytic
Red cell size	Macrocytic	Normocytic or macrocytic	Macrocytic	Normocytic
Bone marrow erythroblasts				
Light microscopy	Megaloblastic, binucleated (2% to 5%), chromatin bridges	Normoblastic, binucleated (10% to 40%)	Gigantoblasts (10% to 40%)	Binucleate forms, nuclear budding, rare karyorrhexis
Electron microscopy	Spongy "Swiss-cheese" appearance of heterochromatin (60%)	Peripheral double membranes	Nonspecific, intranuclear clefts, karyorrhexis	Rare immature erythroid cells with marked heterochromatin
Altered red cell proteins	Low levels of protein 4.1, impaired globin synthesis	Abnormal glycosylation of bands 3 and 4.5, reticular endoplasmic proteins		Markedly increased red cell adenosine deaminase, absence of In(Lu) unique blood group phenotype, Co(a-b-), In(b-), and LW(ab-) and Lu(b+), low/lack CD44, low/lack AQP1, low BCAM and ICAM4
Acid serum hemolysis (Ham test)	Negative	Positive	Negative	Negative
Agglutinability				
Anti-i	Normal	Strong	Slight	
Anti-I	Slight	Strong	Slight	
Glycosylation	Some abnormalities	Markedly abnormal	Some abnormalities	
Fetal hemoglobin				Markedly elevated
Congenital abnormalities	(+/–) limb[732-734]			Multiple anomalies in 1 patient
Red blood cell transfusion requirement	In children, rarely in adults		Rarely	Frequent
Iron overload	Frequent, independent of red blood cell transfusions	Frequent, independent of red blood cell transfusions	No	Frequent, independent of red blood cell transfusions
Extramedullary erythropoiesis	Sometimes			Erythroid expansion
Gallstones	Frequent			
Hepatosplenomegaly	Mild	Mild		Hepatomegaly, severe splenomegaly
Splenectomy	Usually not recommended	96%	100%	Performed in 1 patient associated with clinical improvement
Interferon-alfa	Effective in majority of patients

*Gene locus for some, but not all, patients in each category.

†Mutated in the majority of patients but not all patients with CDA type I.

‡Mutated in the familial form but not the sporadic form of CDA type III.

Table 7-11. The acidified serum lysis test is negative, and red cells usually show normal agglutinability with anti-i. The cause of the unbalanced globin chain synthesis in some patients with CDA type I is not known.[535]

Patients with CDA type I mount a substantial hematologic response to recombinant interferon alfa-2a or alfa-2b. Long-term interferon alfa therapy has been shown to reduce iron overload. The basis of the response to interferon is not known.[530,531]

Genetic Characteristics. CDA type I is inherited as an autosomal recessive disease. Homozygosity mapping of Israeli Bedouin families localized the gene responsible for CDA type I to chromosome 15q15.1-15.3 and led to identification of the responsible gene, named *CDAN1*.[540] *CDAN1* has 29 exons and encodes a putative 1226–amino acid protein termed codanin-1. The function of codanin-1 is part of a cytosolic complex regulating S-phase histone supply and acts as a negative regulator of chromatin assembly. Depletion of codanin-1 accelerates the rate of DNA replication, whereas overexpression arrests S-phase progression.[541] CDAN1 mRNA is found at low levels in a wide variety of tissues. The majority of mutations in *CDAN1* are missense mutations causing single–amino acid substitutions in the mutant protein. Nonsense mutations, splice-site mutations, and nucleotide insertions or deletions causing a shift in the open reading frame are rare. Homozygosity for 3238 C→T mutation causing an arginine-to-tryptophan substitution at amino acid position 1040 (R1040W) was identified in 45 Bedouin and 11 Israeli Arab families, which suggests a founder effect in these populations. No homozygotes or compound heterozygotes for *CDAN1* null mutations have been identified, indicating that residual codanin-1 function is essential during development. In some families with classic CDA type I, the disease does not segregate with chromosome 15q15.1-15.3, suggesting that the disease is genetically heterogeneous.[539,542]

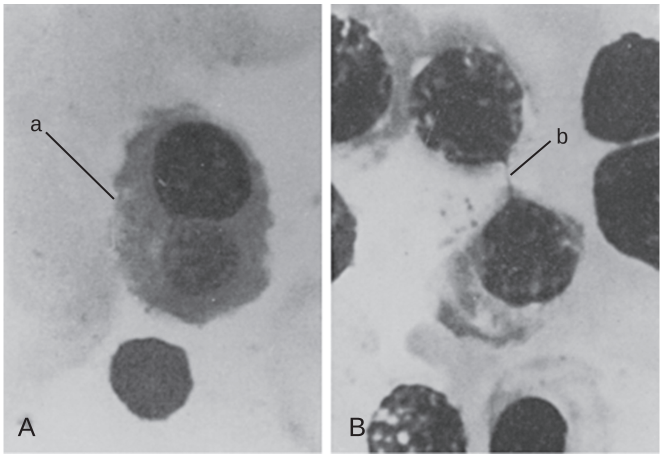

Figure 7-23 Bone marrow from a patient with congenital dyserythropoietic anemia type I. **A,** Small letter a indicates binucleate erythroblast, with nuclei of different size and maturity. **B,** Small letter b indicates internuclear chromatin bridges connecting two erythroblasts. *(From Lewis SM, Verwilghen RL, editors:* Dyserythropoiesis *London, 1977, Academic Press.)*

Congenital Dyserythropoietic Anemia Type II

Clinical Characteristics. The incidence of CDA type II is about 1 in 100,000 births per year, and with more than 300 reported cases, CDA type II is the most frequent form of CDA. The prevalence of CDA II varies widely, with the highest prevalence in Italy (2.49 cases/million).[543] CDA type II is also known as hereditary erythroblastic multinuclearity with a positive acidified serum lysis test (HEMPAS, see later).[525,544] The extent of anemia in patients with CDA type II varies from mild to severe. About 10% of patients require red cell transfusions in infancy and childhood but rarely thereafter.[545] Splenomegaly and the development of gallstones are common.

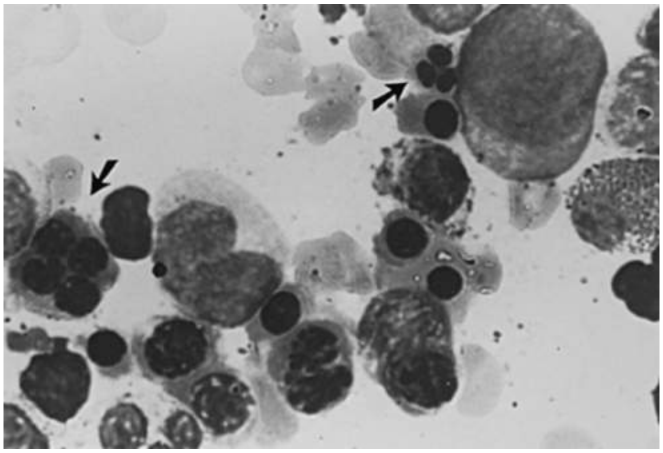

Figure 7-24 Bone marrow from a patient with congenital dyserythropoietic anemia type II, showing binucleate and multinucleate erythroblasts. *(Courtesy of Dr. Gail Wolfe; From Alter BP: The bone marrow failure syndromes. In Nathan DG, Oski FA, editors:* Hematology of infancy and childhood, *3rd ed. Philadelphia, 1987, WB Saunders, p. 159.)*

Extramedullary hematopoiesis with the development of paravertebral tumors is rare.[545,546] Progressive iron overload is seen even in untransfused patients, and liver cirrhosis secondary to iron overload develops in about 20%.

Dysmorphic features appear to be less common than in CDA type I. Mental retardation has been reported in some patients with CDA type II.

Laboratory Findings. Hemoglobin in patients with CDA type II is generally between 8 and 11 g/dL, with a normal mean corpuscular volume.[545] Red cells are usually normocytic, with moderate to marked anisocytosis, anisochromasia, and poikilocytosis (including teardrop-shaped poikilocytes); occasional basophil stippling cells; and a few circulating erythroblasts. There is normoblastic erythroid hyperplasia in the bone marrow, with 10% to 35% of binucleate erythroblasts and, rarely, multinucleate late polychromatic erythroblasts (Fig. 7-24). Pseudo-Gaucher macrophages with birefringent needles may be found in the majority of cases.[545] Electron microscopy shows stretches of double membrane parallel to the inner surface of the erythroblast cell membrane that represent excess proteins containing smooth endoplasmic reticulum, which are normally found in this organelle (i.e., calreticulin, glucose-regulated protein [GRP78], and protein disulfide isomerase).

The red cells of most patients with CDA type II are lysed in the acidified serum lysis test (Ham test) when mixed with 30% to 60% of fresh ABO-compatible normal sera but not the patient's own serum.[544] The reactive sera contain a naturally occurring IgM antibody that recognizes an antigen present on CDA type II cells but not on normal cells. CDA type II red cells show increased agglutinability with anti-i antibody. In contrast to red cells from patients with paroxysmal nocturnal hemoglobinuria, which lyse in the acidified serum lysis test even with autologous serum because of complement activation, CDA type II cells lyse because of persistence of the "HEMPAS antigen" on their surfaces. Thus CDA type II cells do not lyse in the sucrose lysis test.

Incomplete processing of N-linked oligosaccharides leads to defective glycosylation of several usually highly glycosylated membrane proteins such as band 3 (the anion transport protein), band 4.5 (glucose transporter 1), and glycophorin A.[547,548] It has been speculated that an abnormality in the endoplasmic reticulum may be responsible for the defective glycosylation of red cell membrane constituents in CDA type II. Interestingly, abnormal glycosylation has also been found in other proteins such as serum transferrin (synthesized by hepatocytes).

Genetic Characteristics. Inheritance of CDA type II has an AR pattern. Genome-wide linkage analysis has localized the disease gene (*CDAN2*) to a 5-cM region of chromosome 20q11.2. This has led to identification of the *SEC23B* gene encoding the SEC23B component of the coat protein (COP) II complex as the gene responsible for the vast majority of CDA II cases.[549,550] Over 60 different mutations have been identified in patients with CDA II, including missense, frameshift, nonsense, and splice-site mutations.[549-552] There is no clear phenotype-genotype correlation. No patients with biallelic *SEC23B* null mutations have been identified, suggesting that complete protein deficiency is lethal. COP II protein complex–coated vesicles transport proteins from the endoplasmic recticulum to the Golgi apparatus. Mutations in SEC23B result in a misglycosylation and impaired clearance of the endoplasmic recticulum, accounting for the accumulation of endoplasmic reticulum proteins on the periphery. However, the specificity of the disease phenotype to erythropoiesis and its effect on cell division leading to the multinuclearity in erythroid cells remain to be determined. Interestingly, SEC23B and codanin-1 have been shown to colocalize, suggesting a shared disease pathway.[553]

In rare families, the disease gene is not linked to chromosome 20q11.2, a finding indicative of genetic heterogeneity.[554]

Congenital Dyserythropoietic Anemia Type III

CDA type III is rare, with about 60 cases reported, the majority in Sweden. Both familial and sporadic cases have been reported. In familial cases the inheritance pattern is AD. Splenomegaly was present in some patients but not in others. In contrast to CDA types I and II, iron overload seems not to be clinically significant in patients with familial CDA type III, most likely because of intravascular hemolysis and iron loss by hemosiderinuria. Visual disturbances with macular degeneration and angioid streaks, monoclonal gammopathy of undetermined significance, and myeloma have been described in individual families.[555] Sporadic CDA type III cases are clinically heterogeneous. Hepatosplenomegaly and significant iron overload have been described in some.[556]

Laboratory Findings. Anisopoikilocytosis, basophilic stippling of red cells, and some very large red cells may be found in the peripheral blood smear. Serum thymidine

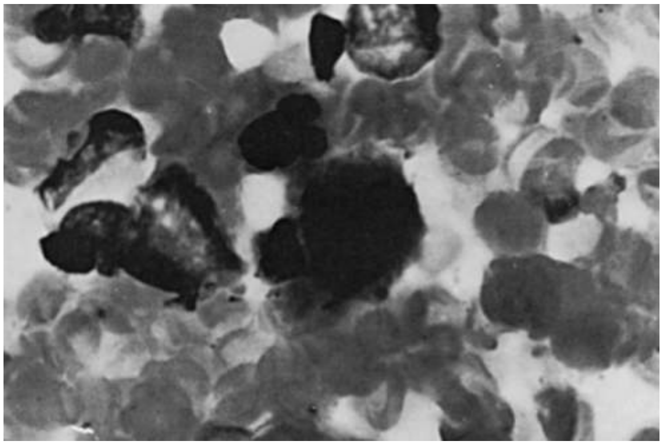

Figure 7-25 Bone marrow from a patient with congenital dyserythropoietic anemia type III, showing multinucleate erythroblast. *(Courtesy of Dr. Gail Wolfe; From Alter BP: The bone marrow failure syndromes. In Nathan DG, Oski FA, editors:* Hematology of infancy and childhood, *3rd ed. Philadelphia, 1987, WB Saunders, p. 159.)*

kinase activity is elevated in most patients with CDA III. In families with hemosiderinuria, iron deficiency may be found. The bone marrow contains multinucleate and mononucleate erythroblasts (Fig. 7-25).[557,558] Other dysplastic changes include basophilic stippling, nuclear lobulation, and karyorrhexis. Erythroblasts show a variety of nonspecific ultrastructural abnormalities, intranuclear clefts, karyorrhexis, abnormalities in the nuclear membrane, and large autophagic vacuoles.[558] Giant multinucleate and mononucleate erythroblasts may also be seen in MDS and erythroleukemia.

Linkage analysis in one large multiplex family localized the disease gene (*CDAN3*) to chromosome 15q22, distal to the *CDAN1* gene.[559] Array-based sequence capture identified a point mutation (c.2747C→G p.P916R) in *KIF23* encoding mitotic kinesin-like protein 1 (MKLP1) that segregated with disease and seems to be responsible for CDA III in all Swedish and American families.[560] MKLP1 plays critical roles in cytokinesis, accounting for the large multinucleated erythroid progenitor cells characteristic of CDA III.[560]

Congenital Dyserythropoietic Anemia Type IV

CDA IV is exceedingly rare; only four patients have been described. All have severe hemolytic anemia with hyperbilirubinemia, a markedly elevated fetal hemoglobin of 40% or higher, iron overload, and marrow showing moderate dyserythropoiesis. Additional features include splenomegaly and growth delay.

Laboratory Findings. In one case CDA IV was associated with additional complex congenital anomalies (see Table 7-11). Patients with CDA IV have a specific red cell phenotype that is Co(a-b-), In(b-), and LW(ab-) and not the In(Lu). Additional characteristics of CDA IV are the low expression of or lack of expression of CD44 and AQP1, as well as low expression of BCAM and ICAM4. Some patients also have persistent expression of embryonic globins.

Genetic Characteristics. All four reported patients are heterozygous for a G-to-A transition in exon 3 of the *KLF1* gene, resulting in an E325K substitution in erythroid-Krüppel–like factor (EKLF), an erythroid specific transcription factor essential for the patterns of erythroid gene expression. KLF1 expression plays a critical role in the switch from fetal to adult globin[561] and also regulates CD44 and AQP1 expression on red cells. *KLF1* mutations lead to a number of distinct human disorders, including the lack of the Lutheran group antigen, hereditary persistence of the fetal hemoglobin, and CDA II. The mutation E325K is thought to have a dominant negative effect.[561] The Nan (severe neonatal anemia) mouse has a hemolytic anemia that displays many of the features of CDA III, and hereditary spherocytosis carries a mutation in the same conserved EKLF1 amino acid.[562]

Additional Variants of Congenital Dyserythropoietic Anemia

A number of forms of CDA cannot be classified as type I, II, III or IV. In a tentative phenotype-based classification, some of them have been assigned to four groups designated CDA group V, VI, and VII, consisting of three or more unrelated families.[556,563] In addition, there are several reports of individual families who have not been further classified.

There are a number of other conditions that have congenital dyserythropoietic anemia as part of their syndromic manifestations, such as Majeed syndrome caused by mutations in *LPIN2* (18p11.31),[564] a syndromic case of dyserythropoiesis associated with exocrine pancreatic insufficiency caused by *COX4I2* mutations,[565] and a patient with two causative mutations in the mevalonate kinase gene (*MVK*).[565]

Congenital Dyserythropoiesis Associated with Thrombocytopenia

X-linked dyserythropoiesis with thrombocytopenia (MIM 305371) is not usually considered a form of CDA; nevertheless, it is associated with mild dyserythropoiesis. X-linked congenital dyserythropoiesis with thrombocytopenia results from mutations in the transcription factor *GATA1*, which cause several hematologic conditions with overlapping phenotypes. These include recessive X-linked thrombocytopenia and mild dyserythropoiesis, X-linked thrombocytopenia with the thalassemia minor phenotype, X-linked Lu(a-b-) phenotype, and mild dyserythropoiesis and red cell aplasia similar to DBA (see DBA section).[473] Because bleeding secondary to thrombocytopenia plus impaired platelet function is the major clinical feature, X-linked dyserythropoiesis with thrombocytopenia is discussed in more detail with the inherited thrombocytopenias (see Chapter 30).

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN, MIM 202700) is a heterogeneous group of disorders first described in an extended consanguineous family by the Swedish physician Rolf Kostmann (Box 7-19).[566,567] The disease has thus also been known as *Kostmann syndrome*, although this eponym has since been used to define a subset of patients with AR inheritance of SCN. The incidence of

Box 7-19 **Severe Congenital Neutropenia Associated with *ELANE* Mutations**

Approximately 60% of cases of severe congenital neutropenia are associated with heterozygous mutations of *ELANE* (MIM #202700). This disorder is characterized by chronic severe neutropenia (absolute neutrophil count <500 cells/µL) and is associated with an arrest in myeloid maturation at the promyelocyte/myelocyte stage of granulocytic differentiation. Affected patients have marked susceptibility to infection and a very high risk of progression to acute myeloid leukemia.

SCN is estimated to be approximately 1 to 10 cases per million, and both genders are affected equally. SCN has been reported in a broad range of ethnic groups, although there is evidence that the incidence of SCN may be lower in American blacks than in the general U.S. population.[401]

Clinical Manifestations

SCN is characterized by severe neutropenia at birth, with ANCs generally below 200 cells/µL. With infection there may be an increase in neutrophils in blood, but this is always transient and usually modest. Other hematologic parameters are generally normal, although peripheral monocytosis and eosinophilia are often observed.[568] Bone marrow cellularity is normal to slightly decreased.[569] In the majority of patients, there is an arrest in myeloid maturation, with a relative, but not absolute, increase in promyelocytes or myelocytes (Fig. 7-26). The promyelocytes often display vacuolization.[570] Bone marrow eosinophilia and monocytosis are common.[569] The number of progenitors committed to the granulocyte lineage is reduced, and they display decreased responsiveness to G-CSF in vitro.[571-574]

Patients with SCN are prone to infections from birth and may initially have omphalitis.[575] In half of patients, infections develop during the first month of life and in 90% by 6 months. Common types of infection include mouth ulcers, gingivitis, cellulitis, skin abscesses, and otitis media. Gingivitis is a frequent problem during early childhood and can lead to premature tooth decay and loss.[576] Pneumonia and deep-tissue abscesses occur frequently and may be life threatening. Indeed, despite therapy with G-CSF, death due to infection remains a major concern in SCN, with a 12% cumulative incidence of death due to sepsis after 15 years of G-CSF therapy.[354,577] The most common causes of infection are *Staphylococcus* and *Streptococcus* species.

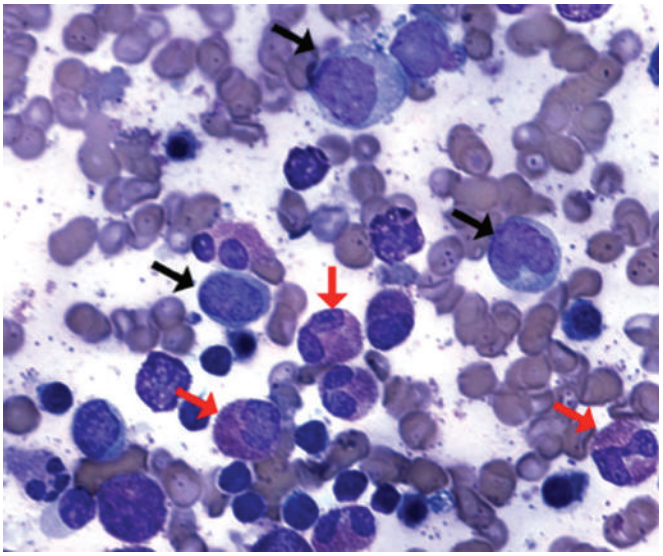

Figure 7-26 Bone marrow aspirate from a patient with SCN showing a paucity of mature neutrophils, relative accumulation of promyelocytes *(black arrows)*, and marrow eosinophilia *(red arrows)*.

There is a high incidence of osteopenia in patients with SCN. In the 422 patients with SCN enrolled in the Severe Chronic Neutropenia International Registry (SCNIR), 28% had bone mineral density measurements or radiographic examinations performed as part of routine care.[401] In this subgroup of patients there was evidence of osteopenia in nearly half. Moreover, pathologic fractures, particularly in vertebrae, have been reported in a substantial minority of patients.[578-580] Although chronic G-CSF treatment has been shown to induce osteopenia in mice,[581] the relationship of long-term G-CSF treatment in humans to osteopenia remains uncertain. A small trial suggested that treatment with bisphosphonates improves the osteopenia in patients with SCN.[579] Given the high incidence of osteopenia and potentially effective therapy, it is reasonable to perform periodic assessment of bone mineral density in all patients with SCN.

Predisposition to Malignant Disease

Patients with SCN have a markedly increased risk for MDS or AML.[354,577,582-584] The North American SCNIR has an ongoing prospective observational study of 374 patients with SCN. The most recent update from this study showed that the cumulative incidence of MDS/AML was 22% after 15 years of G-CSF therapy (Fig. 7-27). Of note, the estimated hazard rate of MDS/AML is approximately 2% per year even after 10 years of G-CSF therapy. Thus the total percentage of patients at risk for MDS/AML is likely to be very high. Similar high rates of transformation to MDS/AML were reported in a Swedish cohort of 21 patients with SCN (31% at 15 years)[582] and a French cohort of 101 patients with SCN (11% at 20 years).[583] Approximately half of patients in whom myeloid malignant tumors develop are found to have MDS, typically classified as refractory anemia with excess blasts.[354,584] A consistent feature of myeloid transformation in SCN is the high rate of chromosome 7 abnormalities. In the largest series, nearly 60% of AML/MDS samples displayed complete or partial loss of chromosome 7.[584]

Both the dose of G-CSF and the neutrophil response to G-CSF are predictive of transformation to MDS/AML. In the subgroup of patients that received more than the median dose of G-CSF (>8 µg/kg/day) but achieved less than the median neutrophil response (ANC <2188/µL), the cumulative incidence of MDS/AML was 34% at 15 years of G-CSF therapy.[577] This compares with a cumulative risk of MDS/AML of 15% at 15 years in patients who responded well to a lower dose of G-CSF (ANC

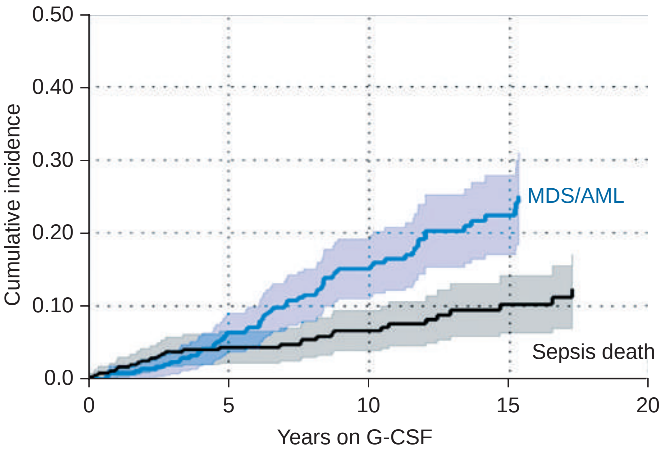

Figure 7-27 Cumulative incidence (cumulative proportion experiencing each event as initial cause of failure, in patients at risk for each adverse event) of myelodysplastic syndrome/acute myeloid leukemia or death from sepsis by years on therapy with granulocyte colony-stimulating factor. The 95% confidence intervals are indicated by the shaded regions. *(From Rosenberg PS, Zeidler C, Bolyard AA, et al: Stable long-term risk of leukaemia in patients with severe congenital neutropenia maintained on G-CSF therapy.* Br J Haematol *150:196–199, 2010.)*

≥2118/μL taking G-CSF ≤8 μg/kg/day). MDS/AML has been reported in patients with SCN associated with *ELANE* or *HAX1* mutations and in SCN of unknown etiology.[577,582] Of note, the risk of MDS/AML may be less in patients with *G6PC3* mutations. In a cohort of 28 patients with *G6PC3* mutations and SCN, no cases of MDS/AML were observed with 291 person-years of observation.[585] Malignant transformation is rare (<1%) in individuals with cyclic neutropenia or idiopathic neutropenia.[354]

Differential Diagnosis

A detailed discussion of secondary neutropenia, including immune-mediated, drug-related, and infection-related neutropenia, is provided in the section on the phagocytic system. Inherited causes of moderate to severe neutropenia are shown in Table 7-12. Cyclic neutropenia (MIM 162800), which shares the same gene mutation (*ELANE*) as most cases of SCN, is characterized by 21-day oscillations in the number of circulating neutrophils.[586,587] *WHIM syndrome* (MIM 193670) (warts, hypogammaglobulinemia, infections, and myelokathexis) can be distinguished from SCN by noting a normal to increased number of mature neutrophils in bone marrow and the presence of *CXCR4* mutations in most cases.[588-590] Both cyclic neutropenia and WHIM syndrome are covered in

detail in the phagocytic section (see Chapter 22). The other disorders can be distinguished by the presence of associated clinical features, including exocrine pancreatic insufficiency (SDS), cardiomyopathy (Barth syndrome), lactic acidosis (PS), hypoglycemia (glycogen storage disease type Ib), partial albinism (Chédiak-Higashi, Griscelli, or p14 deficiency syndromes),[591] rash/poikiloderma (poikiloderma with neutropenia),[592] and dysgammaglobulinemia (hyper-IgM syndrome)[593-595]; each of these disorders is discussed in detail elsewhere in this text. Genetic testing is becoming an increasingly important tool in the diagnosis of congenital neutropenia.[596] Clinical genetic testing for mutations of many of the genes listed in Table 7-12 is available.

Genetic Characteristics and Pathophysiology

SCN demonstrates multiple modes of inheritance, including AR, AD, X-linked, and sporadic patterns. Accordingly, recent genetic studies have identified multiple gene mutations in SCN, including *ELANE* (formerly *ELA2*) (MIM 202700), *HAX1* (MIM 610738), *G6PC3* (MIM 611045), *GFI1* (MIM 613107), *CSF3R* (MIM 162830), and *WAS* (MIM 300299). In approximately 30% of cases of SCN, the genetic basis has not yet been identified. By far the most common mutations affect the *ELANE* gene encoding neutrophil elastase, which accounts for approximately 60% of all cases (all in AD or sporadic SCN).[597-599,600] To date, more than 100 distinct mutations of the *ELANE* gene have been reported in patients with cyclic neutropenia or SCN. Most of the mutations (≈70%) are missense mutations, although mutations that lead to alternative splicing (≈10%), frameshifts (≈10%), and premature stop codons (≈10%) have also been observed. Although specific *ELANE* mutations are typically associated with either SCN or cyclic neutropenia, some specific *ELANE* mutations are associated with both, suggesting that modifying genes determine the severity of neutropenia.[601]

The molecular mechanisms by which *ELANE* mutations disrupt granulopoiesis are unclear. Genetic studies provide two important clues. First, in all cases the *ELANE* mutations are heterozygous, which suggests a dominant mechanism of action. Second, a case report of paternal mosaicism for an *ELANE* mutation provides evidence that expression of mutant neutrophil elastase inhibits granulopoiesis in a cell-intrinsic fashion because no toxic paracrine effects of mutant neutrophil elastase on wild-type granulocytic cells in this mosaic individual were observed.[602] Neutrophil elastase is a serine protease stored in the primary (azurophilic) granules of neutrophils and (at a much lower level) in monocytes. Although the physiologic substrates have not been fully defined, there are many recognized and potential substrates for neutrophil elastase, including coagulation proteins, growth factors, and extracellular matrix components.[603] However, no consistent effect of *ELANE* mutations on neutrophil elastase proteolytic activity, substrate specificity, or serpin inhibition has been observed.[604] Though still controversial, the current model of disease pathogenesis suggests that *ELANE* mutations disrupt granulopoiesis through induction of the unfolded protein response (UPR).[605-607] In this model, *ELANE* mutations result in the production of misfolded neutrophil elastase protein, which accumulates in the endoplasmic reticulum, activates the UPR, and ultimately induces apoptosis of granulocytic precursors. The propensity of individual neutrophil elastase mutants to misfold may determine the magnitude of UPR-induced apoptosis and ultimately the clinical phenotype. Thus SCN may represent one of a growing number of disorders caused by protein misfolding.

Biallelic mutations of *HAX1* are associated with autosomal recessively inherited SCN (i.e., Kostmann syndrome).[608] The reported incidence of *HAX1* mutations in SCN varies widely in different cohort studies, ranging from 0% to 41% (mean 8.9%).[582,599,609-612] Of note, HAX1 is alternatively spliced to produce two major transcripts. Mutations that affect both types of HAX1 transcripts are associated with neurologic abnormalities, including seizures and developmental delay.[609] HAX1 is a Bcl-2–related protein that has antiapoptotic activity and is localized to mitochondria.[613,614] Thus increased susceptibility of granulocytic precursors to apoptosis is one likely mechanism of disease pathogenesis in *HAX1*-mutant SCN. However, HAX1 also has been implicated in the activation of lymphoid enhancer–binding factor 1 (LEF-1),[615] a transcription factor regulated by the canonical Wnt signaling pathway. Since reduced LEF-1 expression in granulocytic precursors from patients with SCN has been reported,[616] these data suggest that loss of LEF-1 activity also may contribute to the block in granulocytic differentiation in SCN.

Bi-allelic mutations of *G6PC3* are another cause of autosomal recessively inherited SCN.[617] The overall incidence of *G6PC3* mutations in unselected patients with SCN is approximately 4%.[599,612,618] SCN associated with *G6PC3* mutations is often, but not always,[619] associated with nonhematopoietic features, including congenital heart disease, prominent superficial veins, abnormal facial appearance, urogenital abnormalities, and intermittent thrombocytopenia.[585,617] *G6PC3* encodes for glucose-6-phosphatase catalytic subunit 6. G6PC3 deficiency is associated with increased granulocytic precursor apoptosis, possibly through activation of the UPR.[617]

An X-linked form of SCN linked to germline mutations in the *WAS* gene has been identified.[620-623] Unlike classic WAS, which results from loss-of-function mutations, WAS-associated X-linked neutropenia appears to result from gain-of-function mutations of *WAS* that disrupt an autoinhibitory domain of the WAS protein. In contrast to most cases of SCN where monocytosis is common, SCN associated with *WAS* mutations presents with monocytopenia.[599,623] Thus monocytopenia in a patient with SCN should prompt a search for *WAS* mutations. Activating mutations of WAS result in enhanced actin polymerization and genomic instability.[624,625]

Heterozygous mutations of *CSF3R* and *GFI* are rare causes of sporadic SCN. *CSF3R* encodes the G-CSF receptor. The *CSF3R* mutations in SCN are thought to act in a dominant negative fashion by inhibiting receptor trafficking to the cell surface and heterodimerization in response to G-CSF.[626-628] SCN associated with *CSF3R* mutations presents with unusually severe neutropenia that is refractory to suprapharmacologic doses of G-CSF. *GFI1* encodes a zinc-finger domain transcriptional repressor. The *GFI1* mutations are in the zinc-finger domains and are thought to generate a dominant negative GFI1 mutant protein.[629] Once again, the phenotype of SCN associated with *GFI1* mutations is distinct from that observed in classic SCN in that perturbations in lymphocyte production and function are not typically seen in SCN associated with *ELANE* mutations.

The genetic factors that contribute to transformation to MDS/AML in patients with SCN are not well defined. Indeed, the spectrum of mutations found in SCN-associated AML is distinct from that seen in de novo AML; whereas mutations in *NPM1, FLT3, KIT*, and *CEBPA* are relatively common in de novo AML, they are rare in SCN-related AML.[630] Conversely, mutations of the G-CSF receptor (*CSF3R*) are uniquely associated with the development of AML or MDS in patients with SCN.[631-634] Of note, these mutations are distinct from the previously discussed germline mutations that affect the extracellular domain of the G-CSF receptor and are thought to inhibit G-CSF signaling in a dominant negative fashion. Instead, these are acquired mutations that introduce a premature stop codon that results in truncation of the distal cytoplasmic portion of the G-CSF receptor and enhanced signaling. In the largest published series, the incidence of G-CSF receptor mutations was 78% (18/23) in individuals with SCN and monosomy 7, MDS, or AML versus 34% (43/125) in individuals without signs of malignant transformation.[633]

Studies in mice show that these mutations enhance proliferative signaling by the G-CSF receptor,[635,636] confer a clonal advantage to hematopoietic stem cells,[625] and cooperate with another oncogene to induce AML.[637] Moreover, a recent study showed the sequential acquisition of two distinct G-CSF receptor mutations in a patient with SCN who evolved to AML.[619] Together, these data strongly implicate G-CSF receptor mutations in the leukemic transformation in patients with SCN.

Clinical Management

Historically, patients with SCN had a poor prognosis and often succumbed in the first or second decade of life with recurrent severe bacterial infections. The use of G-CSF has changed the natural history of this disease; the results of a randomized phase III trial comparing G-CSF therapy with no treatment in patients with SCN demonstrated that the majority (>90%) of patients had a significant increase in circulating levels of neutrophils and a reduction in the incidence and severity of bacterial infections.[638] There is substantial patient-to-patient variability in the dose of G-CSF that is required to achieve an acceptable neutrophil count, with some children requiring only 1 to 2 μg/kg on alternate days and others responding only to doses of 50 to 100 μg/kg/day. The SCNIR currently recommends a starting dose of 5 μg/kg/day with upward twofold increases in dose until the ANC level in blood is 1000 to 1500/mL.[401] Recognized adverse effects of chronic G-CSF therapy include splenomegaly, bone pain, and vasculitis. There are case reports of patients who are refractory to G-CSF treatment alone but respond to combination therapy with G-CSF and glucocorticoids.[626] Of note, GM-CSF treatment is not effective in SCN; it increases circulating eosinophils but not neutrophils.[568] In addition to G-CSF treatment, patients with SCN should receive regular and frequent dental care because the rate of periodontal disease remains high despite G-CSF treatment.[576]

Hematopoietic Stem Cell Transplantation. Allogeneic stem cell transplantation is the only current curative therapy for SCN. A recent review of HSCT in SCN identified 65 patients transplanted without malignant transformation; overall and event-free survival rates were 89% and 75%, respectively.[639] Although highly dependent on the donor source and conditioning regimen, the incidence of acute and chronic GVHD was 34% and 11%, respectively. As expected, results of HSCT in SCN patients with MDS/AML are much poorer, with an overall survival rate of only 44%.[517,639-641] Current widely accepted indications for HSCT in patients with SCN include inadequate neutrophil response to G-CSF and the development of MDS or AML. A more difficult question is when to perform transplantation in SCN patients who are doing well with G-CSF and have an HLA-matched sibling donor. The SCNIR data show that in the subgroup of patients that received more than the median dose of G-CSF (>8 μg/kg/day) but achieved less than the median response (ANC <2188/μL), the cumulative incidence of MDS/AML was 34% at 15 years of G-CSF therapy.[577] Moreover, patients who acquire a G-CSF receptor mutation or monosomy 7 appear to have an elevated risk for the development of MDS or AML.[584,633] Though not confirmed in prospective studies, these criteria may help identify patients who should undergo transplantation.

Leukemia Surveillance and Controversy Regarding Leukemia Promotion by G-CSF. It should be emphasized that there is no definitive proof that G-CSF directly contributes to leukemic transformation. Indeed, reports of AML/MDS in SCN predate the use of G-CSF. Moreover, myeloid malignant diseases are rare in children and adults with cyclic neutropenia despite many years of G-CSF treatment.[354] Thus the contribution of G-CSF to the development of AML/MDS in patients with SCN remains controversial, and therapy with G-CSF should not be withheld from patients with newly diagnosed SCN on this basis. Because of the risk of leukemic transformation in SCN, patients should receive the lowest dose of G-CSF that is required to maintain an acceptable neutrophil count and should undergo yearly bone marrow examination with cytogenetic analysis.

Inherited Thrombocytopenias

Inherited forms of thrombocytopenia are rare. They are summarized in Table 7-13 (for a more detailed discussion see Chapter 30).

Two major forms of inherited thrombocytopenia are discussed in the following sections because of their association with aplastic anemia and because they have to be considered as a possible differential diagnosis in

TABLE 7-13 Inherited Thrombocytopenia Syndromes

Syndrome	**Inheritance**	**Gene Mutation**	**Chromosomal Location**	**Platelet Size MPV (7-11 fl)**	**Thrombocytopenia**	**Associated Findings**
Large Platelets						
MYH9-related thrombocytopenia						Rare progression to MDS/AML

Box 7-20 Congenital Amegakaryocytic Thrombocytopenia

Congenital amegakaryocytic thrombocytopenia (CAMT, MIM #60448) is a rare inherited bone marrow failure syndrome of infancy characterized by isolated thrombocytopenia, paucity or absence of megakaryocytes in bone marrow, and no physical anomalies. Congenital amegakaryocytic thrombocytopenia exhibits autosomal recessive inheritance and is caused by mutations in the thrombopoietin receptor (TPO-R), more commonly known as the protooncogene *MPL*.

individuals with one of the major forms of IBMFSs discussed in this chapter.

Amegakaryocytic Thrombocytopenia

Congenital amegakaryocytic thrombocytopenia (CAMT, MIM 60448) is a rare IBMFS characterized by isolated thrombocytopenia and a paucity or absence of megakaryocytes in bone marrow (Box 7-20).[642] The isolated thrombocytopenia progresses to severe aplastic anemia in the majority of affected children.

Clinical Manifestations

Thrombocytopenia is usually diagnosed within the first week of life because of petechiae and bleeding. The thrombocytopenia is usually severe, but platelet size and morphology are normal. The diagnosis is established by bone marrow examination. Thrombopoietin levels are high, consistent with the lack of megakaryocytes and low platelet counts.[643] Physical anomalies may be present but are generally nonspecific. An increased incidence of psychomotor retardation has been reported.[644] A less severe form of CAMT is associated with moderate or transient thrombocytopenia. In contrast to thrombocytopenia with absent radii (TAR) (see later), the thrombocytopenia in patients with CAMT worsens over the first 10 years of life and progresses to severe aplastic anemia by the second decade. Transformation to MDS or MDS/AML has been reported.[644]

Differential Diagnosis

Severe CAMT has to be distinguished from other IBMFSs associated with thrombocytopenia, such as TAR and WAS (see Chapter 30). CAMT lacks the forearm abnormalities characteristic of TAR and the microthrombocytes characteristic of WAS. Thrombocytopenia and amegakaryocytosis have been reported in patients with Noonan syndrome (MIM 163950), caused by mutations of *PTPN11* (see Chapter 30). Patients with CAMT who progress to aplastic anemia may resemble those with other IBMFSs such as FA and DC. The lack of increased chromosomal fragility in the DEB or MMC test performed on cultured peripheral lymphocytes or fibroblasts, or both, is helpful in strengthening the diagnosis of CAMT. Whether telomere length distinguishes CAMT from DC remains to be determined. Severe CAMT has to be distinguished from a long list of acquired thrombocytopenias (see Chapter 30), in particular, intrauterine infections, immune thrombocytopenia of the newborn caused by antiplatelet antibodies (neonatal alloimmune thrombocytopenia), or antiplatelet antibodies secondary to maternal idiopathic thrombocytopenic purpura.

Genetic Characteristics

CAMT is an AR disorder. Mutations in the thrombopoietin receptor gene *c-MPL* are responsible for the disease.[645] Mutations have been identified throughout the *c-MPL* gene, including nonsense, missense, and splicing mutations. Affected individuals are usually compound heterozygous for *c-MPL* mutations, although homozygous mutations have been reported in consanguineous families. Because of consanguinity in affected families, homozygous *c-MPL* mutations in an affected individual are not uncommon.[644]

Genotype-Phenotype Correlation

Patients with CAMT can be divided in two groups: type I patients have complete loss of functional c-Mpl, whereas type II patients have some residual c-Mpl function. Patients with type II CAMT often show transient improvement in the platelet count and have a later onset of pancytopenia than individuals with type I CAMT.[642,644,646] Pancytopenia may be the initial clinical manifestation of individuals with type II CAMT. Heterozygous mutation carriers may have impaired megakaryopoiesis despite normal platelet counts.[647]

Clinical Management

The initial treatment of individuals with CAMT is supportive therapy consisting primarily of transfusion of irradiated leukocyte-depleted single-donor platelets to prevent serious bleeding. Hematopoietic growth factors and cytokines do not elicit a sustained response in patients with CAMT. HSCT is the only curative treatment of CAMT and should be considered in affected children with a matched sibling donor.[648] Sibling donors heterozygous for a *c-MPL* mutation have been used successfully.[649] HSCT with an unrelated transplant was historically associated with a poor outcome because of regimen-related toxicity and engraftment failure.[644,650,651] Low-intensity conditioning may improve transplant-related mortality and the outcome of HSCT in patients with CAMT.[652] A CAMT patient is likely to be an excellent candidate for future gene therapy because restoration of normal c-MPL in combination with the high levels of endogenous thrombopoietin would provide a selective growth advantage to the corrected hematopoietic stem cell.[653]

Thrombocytopenia with Absent Radii

Thrombocytopenia with absent radii (TAR, MIM 274000) is a rare but well-characterized cause of neonatal thrombocytopenia. The hallmarks of this disorder are shortened forearms as a result of bilateral defects in development of the radii and severe thrombocytopenia at birth.[654]

Clinical Manifestations

Patients with TAR have absent radii but may have normal or hypoplastic thumbs (Fig. 7-28). Other skeletal anomalies may accompany the absent radii, including ulnar shortening, thumb hypoplasia, and scapular

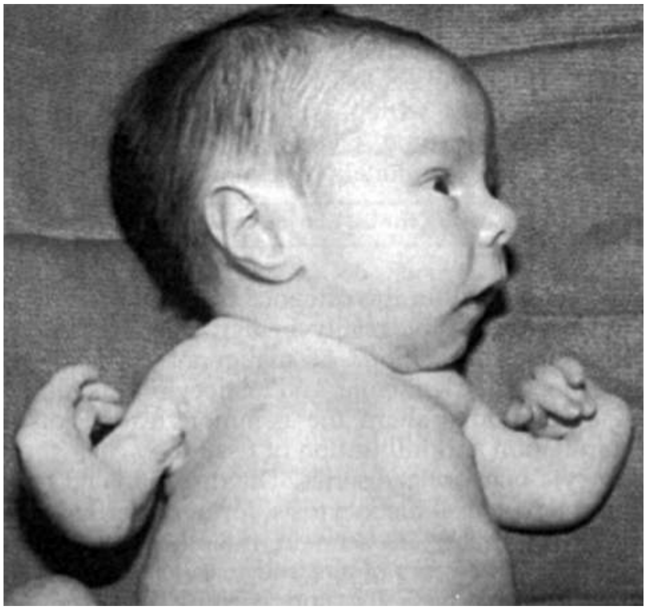

Figure 7-28 Patient with thrombocytopenia with absent radii syndrome. *(From Luchtman-Jones L, Schwartz AL, Wilson DB: The blood and hematopoietic system: diseases of the fetus and infant. In Fanaroff AA, Martin RJ, editors:* Neonatal-perinatal medicine, *7th ed. Philadelphia, 2000, Mosby-YearBook, p. 1235, Figure 44-16.)*

changes. The hands and fingers, however, are not affected. Lower limb abnormalities are frequent but usually less severe and include hip dislocation, patellar anomalies, absence of tibia and fibula joints, and phocomelia, present in about 50% of individuals.[654-657] Common nonskeletal anomalies observed in individuals with TAR include gastroenteritis and cow's milk allergy,[658] genitourinary malformations, cardiac defects, facial dysmorphisms, short stature, macroencephaly, and capillary hemangiomas.[657,659]

Platelet counts in neonates with this condition are generally below 50,000/µl. Platelet size and morphology are normal. Usually, the degree of thrombocytopenia is greatest at the time of birth. Patients demonstrate mucocutaneous bleeding, and platelet transfusions are frequently required in the first year of life. However, thrombocytopenia becomes less severe during the first year of life, and most affected individuals with TAR will not require platelet transfusions after infancy.[656,660] Levels of thrombopoietin are elevated in patients with TAR, yet such patients fail to respond to recombinant thrombopoietin.[661,662] Bone marrow aspiration reveals a decrease in megakaryocytes, although this is not required to make the diagnosis.[663] Eosinophilia and leukemoid reactions have been reported and are usually transient. The development of aplastic anemia has not been observed, but AML and acute lymphocytic leukemia have been reported in patients with TAR.[664-667]

Differential Diagnosis

Although the phenotypes of TAR and FA overlap, several features distinguish these conditions. FA patients are rarely thrombocytopenic in the neonatal period; rather, progressive BMF develops in these patients as children or adults. Only about 30% of patients with FA have a radial defect, whereas this skeletal anomaly is the sine qua non of TAR. In a patient with TAR, thumbs may be present in the absence of radii, whereas in FA, absence of the radius is always accompanied by thumb abnormalities. Despite these differences in clinical features, it is prudent to test patients with a clinical picture of TAR for increased chromosome fragility to formally rule out FA.

Amegakaryocytic thrombocytopenia with radioulnar synostosis (ARTUS, MIM 605432), caused by a mutation in the *HOXA11* gene, is usually associated with mild deformity of the forearms, the inheritance pattern is AD, and severe thrombocytopenia persists, which distinguishes this condition from TAR syndrome.[667,668] Progression to aplastic anemia has been observed in individuals with ARTUS but not those with TAR.

Trisomy 18 can be manifested as radial hypoplasia and thrombocytopenia but is usually associated with esophageal atresia.

Genetic Characteristics

TAR syndrome is caused by compound inheritance of mutations in the *RBM8A* gene, encoding Y14 protein, a component of the exon junction complex that is involved in a variety of cellular functions, including nuclear export of transcripts, translational enhancement, and nonsense-mediated decay.[669] Most individuals with TAR syndrome harbor one null *RBM8A* allele, caused by an interstitial deletion of chromosome 1q21.1,[670] plus one hypomorphic *RBM8A* allele, due to a regulatory SNP in either the 5′-UTR or first intron of the gene.[669] This compound inheritance mechanism results in Y14 protein deficiency, presumably in a cell type– and developmental stage–dependent manner.[669]

Clinical Management

TAR has a much better prognosis than CAMT; the survival curve for TAR plateaus above 70% by 4 years of age. As infants, these patients often require transfusions of single-donor irradiated platelets to maintain a platelet count above 10,000/µL. After the first year of life, platelet transfusion dependence usually diminishes. DDAVP may be helpful for minor bleeding. Recombinant IL-6 has also been reported to lessen the degree of thrombocytopenia in these patients; however, because of considerable side effects, including fever and chills, IL-6 is no longer used for individuals with TAR.[671] Splenectomy improved persistent thrombocytopenia in an adult patient with TAR. In general, HSCT is not indicated. Treatment of nonhematologic manifestations, in particular, orthopedic interventions, dominates the management of TAR later in life. For a detailed discussion of congenital thrombocytopenias, see Chapter 30.
